Accepted 22 July, 2013

Anxiolytic and antidepressant effects and acute toxicity of ethanolic extract (EE) from *Citrus limon* were studied in mice. Anxiolytic activity was evaluated using open field and elevated plus-maze tests. The antidepressant effect of the extract was studied by forced swimming test in mice. Phytochemical screening of the ethanolic extracts indicated the presence of cumarin and triterpenoids/steroids. In the open field test, the oral route administration EE alone showed significant sedative and antidepressant activities in mice (p < 0.05). EE did not alter motor coordination. The EE, at three doses tested, showed antidepressant effect and produced decrease in immobility time. It is concluded that the EE of the aerial parts of *C. limon* have a sedative effect, which may be mediated by benzodiazepine-type receptors, and also an antidepressant effect where noradrenergic and serotonergic mechanisms will probably play a role.

**Key words:** Antidepressant, anxiolytic, *Citrus limon*, ethanolic extract, sedative.

**INTRODUCTION**

Depression and anxiety are the most frequent mental disorders. More than 20% of the adult population suffers from these conditions (Buller and Legrand, 2001). The World Health Organization (WHO, 1999) predicts that depression will become the second leading cause of premature death or disability worldwide by the year 2020. The genus *Citrus* possesses about 70 species of subshrubs and shrubs that can be grown or naturally found in Germany, Spain, Mexico, Venezuela, Cuba, Jamaica, Ecuador and Northern and Northeastern Brazil (Lorenzi and Matos, 2002). The *Citrus* are also known to exhibit various biological activities such as antioxidant (Campêlo et al., 2011a, b; Misharina and Samusenko, 2008), antimicrobial (Choi et al., 2000), anti-inflammatory (Benavente-Garcia and Castillo, 2008), insecticide (Karr and Coats, 1988) and inhibition of acetylcholinesterase (AChE) enzyme (Conforti et al., 2007).

Citrus fruits are known to contain natural antioxidants in its oil, pulp, seed and bark. According to Pereira (Pereira, 1996), the methanol extracts of seeds of lemons has
antioxidant activity. Studies show that ethyl acetate and methanol extract from Citrus limon leaves have anticholinesterase activity as seen with the standard galanthamine, which is considered to be the most effective compound in the treatment of Alzheimer’s disease (Feitosa et al., 2011). Citrus peel and seed represent natural sources of phenolic compounds, including phenolic acids and flavonoids (Bocco et al., 1998).

C. limon Burms (Rutaceae), popularly known as “limão”, has as the major constituents essential oils limonene (52.77%), geranyl acetate (9.92%) and trans-limonene-oxide (7.13%) (Campêlo et al., 2011b). Other studies also showed that C. limon essential oil presents larvicidal activity against Aedes aegypti L. (Furtado et al., 2005). Studies showed the insecticidal properties of d-limonene major constituents of C. limon essential (Karr and Coats, 1988).

Previously, we showed in our laboratory that essential oil of C. limon leaves reduces the lipid peroxidation and nitrite content as well as increase the glutathione reduced (GSH) levels and enzymatic antioxidant activities (superoxide dismutase, catalase and glutathione peroxidase) in mice hippocampus. These findings strongly support the hypothesis that oxidative stress in hippocampus might occur during neurodegenerative diseases, proving that hippocampal damage induced by the oxidative process plays a crucial role in brain disorders, which implies that a neuroprotective effect could be achieved using C. limon essential oil as antioxidant treatment (Campêlo et al., 2011b). Other studies suggest a possible depressant action of C. limon essential oil on central nervous system (CNS) and anticonvulsant activity in seizures model induced by pentylenetetrazole (Campêlo et al., 2011a).

The purpose of the present work was to analyze the effects produced by the acute administration of the ethanolic extract from C. limon using the open field, elevated-plus-maze, rota rod, and forced swimming tests in order to evaluate the anxiolytic and antidepressant activities of this medicinal plant, attempting to clarify their mechanism of action.

MATERIALS AND METHODS

Plant

C. limon was identified and collected by Chistiane Mendes Feitosa in February, 2010, at the city of Picos, state of Piauí, Brazil. The voucher specimen (number 26.453) was deposited at the Graziella Barroso Herbarium of the Federal University of Piauí. Ethanolic extract of C. limon leaves was prepared in Laboratory of Chemistry of Natural Products at Federal University of Piauí, Teresina, Piauí.

Ethanolic extract preparation

The leaves collected from the C. limon were dried at 55°C under shade and powdered mechanically. 10 g of crushed leaves was extracted with water (70%, w/w), followed by ethanol (EtOH) (30%, w/w). The extract was concentrated in a vacuum evaporator. The concentrated extract was finally freeze-dried to get the yield of 10% of ethanolic extract. The dried extract was kept at 4°C in a refrigerator in the air tight bottles until use.

Drugs and reagents

The ethanolic extract (EE) was emulsified with 0.5% Cremophor (Sigma, USA) in distilled water. Diazepam (DZP) was purchased from the (União Química, Brazil) and used as standard. Reserpine sulphate (RESERP) was purchased from the Sigma Chem. Co. (St. Louis, MO, USA). Imipramine (IMI) and Paroxetine (PAROX) were purchased from the Novartis Biociências S.A. (São Paulo, Brazil) and Glaxo Smith Kline Brasil Ltda (Rio de Janeiro, Brazil), respectively. All other drugs were of analytical grade.

Animals and behavioral tests

Male Swiss mice (25 to 30 g) were used. All animals were maintained at a controlled temperature (25 ± 1°C) and a 12-h dark/light cycle. Animals had free access to water and food. All behavioral tests were conducted in quiet rooms at the same controlled conditions referred above. Different groups of mice were used for each behavioral task. For each experiment, mice were randomized into five groups (7 mice per group): one control group treated with the vehicle, three groups treated with EE at 50, 100 and 150 mg/kg, and a fifth drug reference group treated with imipramine (25 or 50 mg/kg; forced swimming test), paroxetine (10 or 20 mg/kg; forced swimming test), reserpine (0.25 mg/kg; forced swimming test) or DZP (0.75 or 2 mg/kg; open field, rota rod). Treatment with EE or vehicle was given orally (p.o.) via gastric gavage (10 ml/kg) for 30 days. All experiments were performed according to the Guide for the Care and Use of Laboratory Animals, from the US Department of Health and Human Services, Washington DC, 1985. Experimental protocols and procedures were approved by the Ethics Committee on Animal Experiments at the Federal University of Piauí (CEEA/UFPJ # 013/2011).

Experimental protocol and behavioral screening

After the treatment, each animal was submitted to a series of tests in the manner described below. Firstly, the animal was observed in a closed room at constant temperature (25 ± 1°C). Then, the animal was placed inside a plus maze and observed for 5 min. Immediately after the plus maze test, it was placed in the open field area for more 5 min. After that, the animal was removed to the rota rod where it was evaluated for 1 min. Finally, its temperature was taken more 5 min after the test.

The behavioral screening of the mice was performed according to the parameters described by Almeida et al. (1999). Animals were observed at 24 h after the EE C. limon administration (50, 100 and 150 mg/kg, p.o.). During 24 h we observed the occurrence of the following general signs of toxicity: piloerection, prostration, writhing, increased evacuation, grooming, discrete groups, dyspnoea, sedation, analgesia and palpebral ptosis.

Open field test

Mice were randomly allocated to the following groups: control (0.05% Tween 80, dissolved in 0.9% saline, p.o.), diazepam (2.0...
mg/kg, i.p.) and ethanolic extract from *C. limon* (50, 100 and 150 mg/kg, i.p.), that received acute treatment acute with single dose before open field test. The open-field arena was made of acrylic (transparent walls and black floor, 30 × 30 × 15 cm), divided into nine squares of equal areas. The open field was used to evaluate the exploratory activity of the animal (Archer, 1973). The observed parameters were the number of squares crossed (with the four paws) and number of grooming and rearing, recorded for 5 min testing period.

**Elevated plus maze test (EPM)**

Mice were randomly allocated to the following groups: control (0.05% Tween 80, dissolved in 0.9% saline, p.o.), diazepam (0.75 mg/kg, i.p.) and ethanolic extract from *C. limon* (50, 100 and 150 mg/kg, i.p.), that received treatment acute with single dose before open field test. This test has been widely validated to measure anxiety in rodents (Lister, 1987). The elevated plus maze (EPM; 30 × 6 × 6 cm, each arm) made of wood and consisting of two open and two closed arms across each other, respectively is placed 60 cm above the ground level. After treatment, the animal was placed at the center of the plus maze with its nose in the direction of one of the closed arms, and observed for 5 min, following the parameters: number of entries in the open and closed arms, and time of permanence in each of them. The time of permanence measures the time spent by the animal in the open and closed arms (Lister, 1987).

**Forced swimming test**

Mice were randomly allocated to the following groups: control (0.05% Tween 80, dissolved in 0.9% saline, p.o.), imipramine (25 and 50 mg/kg, i.p.), paroxetine (10 and 20 mg/kg, i.p.), reserpine (0.25 mg/kg, i.p.), and ethanolic extract from *C. limon* (50, 100 and 150 mg/kg, i.p.), that received treatment acute with single dose before behavioural test. For assessing antidepressant activities, we employed the method described by Porsoi et al. (1977a, b, 1978). The development of immobility when mice were placed inside an inescapable cylinder filled with water reflects the cessation of persistent escape-directed behavior. Briefly, mice were individually placed in a circular tank (46 cm tall × 20 cm in diameter) filled with tap water (25 ± 1°C) to a depth of 20 cm and left there for 5 min. During this period, the behavior of the animals was recorded by an observer. Mice were considered immobile when remained floating without struggling and making only slight movements necessary to maintain the head above the water.

**Rota rod test**

Mice were randomly allocated to the following groups: control (0.05% Tween 80, dissolved in 0.9% saline, p.o.), diazepam (0.75 mg/kg, i.p.) and ethanolic extract from *C. limon* (50, 100 and 150 mg/kg, i.p.), that received acute treatment with single dose before rota rod test. The mice were trained before the experiment to develop the ability to remain for 1 min on a 25 mm diameter rod rotating at 17 rpm. Two or three trials were usually enough for the animals to learn this task. For the rota rod test, for each animal, the number of falls (up to three falls) and the time of permanence on the bar for 1 min were recorded (Dunham and Miya, 1957).

**Rectal temperature**

Animals rectal temperatures were taken at the end of the tests with a digital thermometer.

**Statistical analysis**

Results were expressed as means ± SEM and analyzed with analysis of variance (ANOVA) and the t-Student-Neuman-Keuls as post hoc test (p < 0.05).

**RESULTS**

Phytochemical screening of the ethanolic extracts indicated the presence of cumarin and triterpenoids/steroids and the absence of alkaloids, flavonoids, tannins and saponins. The determination of the chemical constituents was carried out according to the previous methodology proposed (Matos, 2009; Barbosa, 2004). Ethanolic extract from *C. limon* at doses of 50, 100 and 150 mg/kg p.o. caused behavioral changes in animals during 30 days of treatment: decrease of spontaneous activity, palpebral ptosis, ataxia, analgesia, and sedation. Behavioral changes were more evident on the second day of treatments.

In the open field test (Table 1), EE (50 mg/kg, p.o.) decreased in 31% the number of rearings in comparison with the control. Similarly, EE 100 (100 mg/kg, p.o.) and EE 150 (150 mg/kg, p.o.) decreased the number of rearings (31 and 70%, respectively) and also led to grooming reduction. In EE 50 group there was decreased number of crossings by 33% when compared to control. In the same way, EE 100 and EE 150 decreased the number of crossings, as compared to control at the doses used in the present work (51 and 61%, respectively). Diazepam showed sedative effect at the dose used (2 mg/kg, i.p.).

Table 2 shows the effects of EE from *C. limon* in the plus maze test. Among the parameters used for evaluation of the anxiolytic activity, the control group presented the following data: number of entries in the open arms (NEOA); time of permanence in the open arms (TPOA). EE 50 mg/kg (i.p.) decreased NEOA (p < 0.05) and increased TPOA (p < 0.05). Differently, the highest dose of EE decreased NEOA, TPOA (p < 0.01). NEOA and TPOA were also increased by EE, 100 mg/kg i.p. when compared to control. Diazepam (0.75 mg/kg, i.p.) significantly increased all these parameters. An anxiolytic compound reduces the natural animals’ aversion to the open arms and promotes the exploration thereof. On the other hand, the forced or voluntary passages of the animals into the open arms of the EPM are associated with behavioral changes indicative of increased anxiety (Lister, 1987; Hogg, 1966).

The possible antidepressant effect of EE after oral administration was studied in the forced swimming test (Table 3). Under this condition, EE was used at higher doses (50, 100 and 150 mg/kg, p.o.), since at these three doses the antidepressant effect is not masked by the sedative and anxiolytic effects. The results showed that EE presents a significant antidepressant effect (50, 100
and 150 mg/kg), as seen in decreasing of the time of immobility (28, 51 and 70%, respectively). The lowest dose (25 mg/kg) was devoid of any significant effect. The association of EE 150 mg/kg with imipramine (IMI) showed a decrease of 6 and 15% in the immobility time, as related to the groups treated with EE alone (150 mg/kg, p < 0.01) or IMI (p < 0.05) alone, respectively. In addition, the association of EE with paroxetine (p < 0.01) alter the effect observed with EE or paroxetine alone (p < 0.05), suggesting that the serotonergic system is involved in the antidepressant effect of EE. On the contrary, the EE activity was totally blocked by the previous administration of reserpine. These data suggest that the noradrenergic and serotonergic system participates in the EE antidepressant action.

Table 4 shows the effects of EE from C. limon in the rota rod test, a method used for evaluating motor coordination and presence of any muscle relaxation effect. It revealed that there was no change in the number of falls after EE administration (50, 100 and 150 mg/kg, p.o.) when compared to controls (Table 4). Additionally, only EE at 150 mg/kg, p.o. decreased in 18% the time of permanence on the bar in relation to control. Diazepam (0.75 mg/kg, i.p.), like EE 50 and 100, was devoid of effect. The rectal temperature of the control group has been show in Table 5. The doses of 50, 100 and 150 mg/kg, p.o. decreased the rectal temperature, in a dose independent way.

**DISCUSSION**

In the present work, the central effects of the ethanolic extract (EE) of leaves from C. limon were evaluated. EE was firstly analyzed on the open-field test which gives a good indication of the animal's emotional state. The results showed that EE was able to significantly decrease not only the number of crossings, indicative of a possible sedative effect, but also grooming and rearing. The action mechanism of the sedative effect of this EE has not been elucidated yet. However, the reduction in the number of rearings and crossings in the open field test confirms the central activity of this EE, since it is known that rearing is a function of the excitability level of the central nervous system.

Experiments performed as described in materials and methods. Extract ethanolic (EE) was administered orally. Values are the mean ± S.E.M. of time of immobility for 7 mice (per group) used in the experiments. <sup>a</sup>p<0.01 (ANOVA followed by Student-Neuman-Keuls t-test), significantly different from control. <sup>b</sup>p<0.001 (ANOVA followed by Student-Neuman-Keuls t-test), significantly different from EE 50 group. <sup>c</sup>p<0.001 (ANOVA followed by Student-Neuman-Keuls t-test), significantly different from EE 100 group. <sup>d</sup>p<0.001 (ANOVA followed by Student-Neuman-Keuls t-test), significantly different from PAROX 20 group. EE = ethanolic extract; IMI = imipramine; PAROX = paroxetine; RESERP = reserpine. Drugs were administered 10 min before EE and the test performed 30 min later.

These effects are indicative of a dopaminergic-type action (Mora et al., 2005; Almeida et al., 2012). This test is classical model for screening CNS actions, since it provides information about psychomotor performance, anxiety and locomotor activity. It is well known that benzodiazepines act as anxiolytics (at low doses), anticonvulsants, and also produce sedation and a myorelaxant effect at higher doses (Melo et al., 2006). Anxiety, a symptom accompanying various CNS disorders and a disorder by itself, is characterized in humans by a tense and exhaustive physical alertness (Jackson and Turkington, 2005). Other species display a variety of defensive reactions in response to predators, some understood as correlated states of anxiety (Rodgers et al., 1995).

In order to study the possible anxiolytic effect of EE, the elevated-plus-maze test was used. The results showed that EE was able to significantly decrease the time of permanence as well as the number of entrances in the open arms, indicating a negative response. Our results point out that the sedative effects of EE possibly involve the GABA<sub>A</sub> receptor complex. A sedative action was already shown by essential oil of leaves from *C. limon* (Campêlo et al., 2011a) and *Lavandula angustifolia* P.
Miller (Lis-Balchin and Hart, 1999), as assessed by the elevated-plus-maze test in rodents. Active constituents of *C. limon* are primarily monoterpene compounds chemically similar to EE. These monoterpenes exhibit sedative activity that is thought to be due to GABAergic mechanisms. Furthermore, an essential oil from *C. limon* was shown to exert a dose-dependent increase in antioxidant parameters in mice hippocampus (Campêlo et al., 2011b).

The forced swimming test is a behavior test which, in rodents, gives an indication of the clinical efficacy of various types of antidepressant drugs. Nowadays, antidepressants are known to act by several distinct mechanisms at the receptor level, probably also stimulating similar pathways at the sub-cellular level (Yildiz et al., 2002). EE was also able to decrease the immobility time of mice (50, 100 and 150 mg/kg). At higher doses (100 and 150 mg/kg), however, the antidepressant effect was not masked by sedative and hypnotic actions of the drug (data not shown). The EE effect was increased by imipramine, a tricyclic antidepressant (TCA) which blocks the reuptake of both serotonin and norepinephrine. In addition, alterations were seen after EE association with the reuptake of both serotonin and norepinephrine. In addition, alterations were seen after EE association with paroxetine, a known selective serotonin reuptake inhibitor. Additionally, EE effects were totally blocked by the reserpine pretreatment, a known inhibitor of the vesicular catecholamine transporter (that facilitates vesicular storage). A similar process occurs at storage sites for 5-HT, which can finally result in a depletion of biogenic amines. Furthermore, this finding proposes that the antidepressant effect of EE is probably related, at least in part, to the increase in CNS noradrenergic and serotonergic activities.

In order to assess whether the EE produces loss of motor coordination of animals, a test was performed on the rota-rod apparatus. Our results suggest that the highest dose of EE produces loss of motor coordination of mice. This result also suggests that increasing the dose leads to an EE amnesic effect, an important characteristic of the benzodiazepine drugs. Thus, lack of coordination and muscle relaxation in the test of the Rota-rod is characteristic of a drug that reduces the CNS activity such as sedatives and hypnotics (Almeida et al., 2012; Silva et al., 2011). Rectal temperature decreased at all doses tested. This result can probably be associated with possible action on the GABAergic system.

**Conclusions**

Our results gave support to the idea that EE interacts with the GABA<sub>A</sub> receptor, probably at the receptor subtypes that mediate BDZ effects, to produce sedative and hypnotic activities, and also acts to increase the noradrenergic and serotoninergic activities that is the main factor responsible for its antidepressant activity. Additional studies, however, are needed to fully clarify the mechanism of sedative and antidepressant effects of ethanolic extract of leaves from *C. limon*.
