ABOUT IJBMBR

The International Journal for Biotechnology and Molecular Biology Research (IJBMBR) (ISSN 2141-2154) is published Monthly (one volume per year) by Academic Journals.

International Journal for Biotechnology and Molecular Biology Research (IJBMBR) provides rapid publication (monthly) of articles in all areas of the subject such as Green energy from chemicals and bio-wastes, Studies in the graft copolymerization of acrylonitrile onto cassava starch by ceric ion induced initiation, Antimutagenic activity of aqueous extract of Momordica charantia, Ethnomedicinal plants and other natural products with anti-HIV active compounds and their putative modes of action etc.

The Journal welcomes the submission of manuscripts that meet the general criteria of significance and scientific excellence. Papers will be published shortly after acceptance. All articles published in IJBMBR are peer-reviewed.

Instructions for Author

Electronic submission of manuscripts is strongly encouraged, provided that the text, tables, and figures are included in a single Microsoft Word file (preferably in Arial font).

The cover letter should include the corresponding author’s full address and telephone/fax numbers and should be in an e-mail message sent to the Editor, with the file, whose name should begin with the first author’s surname, as an attachment.

Article Types
Three types of manuscripts may be submitted:

Regular articles: These should describe new and carefully confirmed findings, and experimental procedures should be given in sufficient detail for others to verify the work. The length of a full paper should be the minimum required to describe and interpret the work clearly.

Short Communications: A Short Communication is suitable for recording the results of complete small investigations or giving details of new models or hypotheses, innovative methods, techniques or apparatus. The style of main sections need not conform to that of full-length papers. Short communications are 2 to 4 printed pages (about 6 to 12 manuscript pages) in length.

Reviews: Submissions of reviews and perspectives covering topics of current interest are welcome and encouraged. Reviews should be concise and neither than 4-6 printed pages (about 12 to 18 manuscript pages). Reviews are also peer-reviewed.

Review Process
All manuscripts are reviewed by an editor and members of the Editorial Board or qualified outside reviewers. Authors cannot nominate reviewers. Only reviewers randomly selected from our database with specialization in the subject area will be contacted to evaluate the manuscripts. The process will be blind review.

Decisions will be made as rapidly as possible, and the Journal strives to return reviewers’ comments to authors as fast as possible. The editorial board will re-review manuscripts that are accepted pending revision. It is the goal of the AJMR to publish manuscripts within weeks after submission.

Regular articles
All portions of the manuscript must be typed double-spaced and all pages numbered starting from the title page.

The Title should be a brief phrase describing the contents of the paper. The Title Page should include the authors' full names and affiliations, the name of the corresponding author along with phone, fax and E-mail information. Present addresses of authors should appear as a footnote.

The Abstract should be informative and completely self-explanatory, briefly present the topic, state the scope of the experiments, indicate significant data, and point out major findings and conclusions. The Abstract should be 100 to 200 words in length. Complete sentences, active verbs, and the third person should be used, and the abstract should be written in the past tense. Standard nomenclature should be used and abbreviations should be avoided. No literature should be cited. Following the abstract, about 3 to 10 key words that will provide indexing references should be listed.

A list of non-standard Abbreviations should be added. In general, non-standard abbreviations should be used only when the full term is very long and used often. Each abbreviation should be spelled out and introduced in parentheses the first time it is used in the text. Only recommended SI units should be used. Authors should use the solidus presentation (mg/ml). Standard abbreviations (such as ATP and DNA) need not be defined.

The Introduction should provide a clear statement of the problem, the relevant literature on the subject, and the proposed approach or solution. It should be understandable to colleagues from a broad range of scientific disciplines.

Materials and methods should be complete enough to allow experiments to be reproduced. However, only truly new procedures should be described in detail; previously published procedures should be cited, and important modifications of published procedures should be mentioned briefly. Capitalize trade names and include the manufacturer's name and address. Subheadings should be used. Methods in general use need not be described in detail.
Results should be presented with clarity and precision. The results should be written in the past tense when describing findings in the authors' experiments. Previously published findings should be written in the present tense. Results should be explained, but largely without referring to the literature. Discussion, speculation and detailed interpretation of data should not be included in the Results but should be put into the Discussion section.

The Discussion should interpret the findings in view of the results obtained in this and in past studies on this topic. State the conclusions in a few sentences at the end of the paper. The Results and Discussion sections can include subheadings, and when appropriate, both sections can be combined.

The Acknowledgments of people, grants, funds, etc should be brief.

Tables should be kept to a minimum and be designed to be as simple as possible. Tables are to be typed double-spaced throughout, including headings and footnotes. Each table should be on a separate page, numbered consecutively in Arabic numerals and supplied with a heading and a legend. Tables should be self-explanatory without reference to the text. The details of the methods used in the experiments should preferably be described in the legend instead of in the text. The same data should not be presented in both table and graph form or repeated in the text.

Figure legends should be typed in numerical order on a separate sheet. Graphics should be prepared using applications capable of generating high resolution GIF, TIFF, JPEG or Powerpoint before pasting in the Microsoft Word manuscript file. Tables should be prepared in Microsoft Word. Use Arabic numerals to designate figures and upper case letters for their parts (Figure 1). Begin each legend with a title and include sufficient description so that the figure is understandable without reading the text of the manuscript. Information given in legends should not be repeated in the text.

References: In the text, a reference identified by means of an author’s name should be followed by the date of the reference in parentheses. When there are more than two authors, only the first author’s name should be mentioned, followed by ‘et al.’. In the event that an author cited has had two or more works published during the same year, the reference, both in the text and in the reference list, should be identified by a lower case letter like ‘a’ and ‘b’ after the date to distinguish the works.

Examples:
Abayomi (2000), Agindotan et al. (2003), (Kelebeni, 1983), (Usman and Smith, 1992), (Chege, 1998; 1987a,b; Tijani, 1993,1995), (Kumasi et al., 2001)

References should be listed at the end of the paper in alphabetical order. Articles in preparation or articles submitted for publication, unpublished observations, personal communications, etc. should not be included in the reference list but should only be mentioned in the article text (e.g., A. Kingori, University of Nairobi, Kenya, personal communication). Journal names are abbreviated according to Chemical Abstracts. Authors are fully responsible for the accuracy of the references.

Examples:

Short Communications

Short Communications are limited to a maximum of two figures and one table. They should present a complete study that is more limited in scope than is found in full-length papers. The items of manuscript preparation listed above apply to Short Communications with the following differences: (1) Abstracts are limited to 100 words; (2) instead of a separate Materials and Methods section, experimental procedures may be incorporated into Figure Legends and Table footnotes; (3) Results and Discussion should be combined into a single section.

Proofs and Reprints: Electronic proofs will be sent (e-mail attachment) to the corresponding author as a PDF file. Page proofs are considered to be the final version of the manuscript. With the exception of typographical or minor clerical errors, no changes will be made in the manuscript at the proof stage.
Fees and Charges: Authors are required to pay a $650 handling fee. Publication of an article in the International Journal for Biotechnology and Molecular Biology Research is not contingent upon the author's ability to pay the charges. Neither is acceptance to pay the handling fee a guarantee that the paper will be accepted for publication. Authors may still request (in advance) that the editorial office waive some of the handling fee under special circumstances.

Legumes have been used as food by indigenous people of Africa yet their full potential as food sources has not been completely realized. With modern technologies such as marker-assisted selection and mutational breeding, there is scope for rapid improvement of germplasm in these underutilized species. One approach is to induce genetic mutations through irradiation of plant tissues with neutrons or gamma rays generating molecular changes. The irradiation leaves residual radiation in the exposed tissues creating offspring with new features. Genetic mutations in plants can improve their performance, germination, quality, size and disease resistance. The effects of radiation applied to marama bean (Tylosema esculentum) were explored. The aim of this study was to screen individuals of T. esculentum derived from seeds irradiated with gamma rays using microsatellite markers. There were two irradiation treatments -50 and 100 gamma ray irradiations that were compared to non-irradiated seeds as controls. For each treatment, seeds were imbibed and germinated. Seed emergence rates and percentages were ascertained. Each set of seeds was genotyped using a SSR marker - MARA039, located in a sub-unit of a polygalacturonase – an enzyme that mainly regulates seed germination. In regard to emergence, significant differences between the irradiated seeds and non-irradiated counterparts were noted. Irradiated seeds germinated faster and in an dosage-dependent manner compared to non-irradiated counterparts (p>0.05). Genotyping revealed that the total number of AGA repeats in the microsatellite region shifted from its original five in the controls to between four and seven in the irradiated seeds. Furthermore, there were several point mutations in the irradiated seeds as compared to the controls. The study findings, suggest that irradiation may induce beneficial mutational changes such as faster germination rate of the marama bean, considering that the mutated microsatellite repeat region is located in gene encoding the enzyme regulating seed germination in plants.

Key words: Marama bean, Tylosema esculentum, mutational breeding, irradiation, seed cycle, SSR.

INTRODUCTION

Although legumes have been used by the indigenous peoples of Africa for centuries, their full potential as sources of food has never been realized. However, with the advent of modern technologies such as marker-assisted selection and mutational breeding, there is scope for the rapid improvement of plant germplasm in
these underutilized species (Sprent et al., 2010). Among the grain crops, legumes (also known as pulses or food legumes) rank third in the world production behind cereals and oilseeds, and constitute an important dietary constituent for both humans and animals especially where dietary protein is an expensive commodity.

Grain legumes play a crucial role in the sustainability of agricultural systems and in food protein supplies in the developing world. The production of cereals dominates world food production while pulses play an often under estimated role as a break crop that fixes nitrogen (Popelka et al., 2004). Several constraints that limit crop production or the quality of grain legumes have been addressed by conventional breeding and enhanced management, but there are situations where the existing germ plasm still lacks the required traits. Genetic transformation could help provide solutions to certain constraints, and thus improving food security in developing countries (Popelka et al., 2004). With the ever increasing population growth, the demand for food and feed is also increasing, while natural resources are often becoming more and more constrained. Erratic rainfalls, sudden and severe drought conditions as well as excessive floods, often related to climate changes, even further negatively impact on crop production conditions (Reynolds et al., 2009). Thus the yield potential of crop plants has to be significantly increased in order to combat this worsening food security situation.

Marama bean is an arid zone, long-lived perennial legume that generates from an underground tuber (Lawlor, 2004). The scientific name for its species is Tylosema esculentum, a member of the Caesalpinioiodae, in the sub-family of Fabaceae (Castro et al., 2005). Naturally wild and native to the Kalahari sand regions of Namibia and Botswana as well as parts of South Africa (North West and Gauteng Provinces), T. esculentum is part of the staple diet of the indigenous people of these regions (Coetzer and Ross, 1977). The bean compares very well in protein and oil content with both soya and peanut and has been suggested as an alternative crop for domestication in the arid and semi-arid regions of Africa, particularly in the face of climatic changes where rainfall patterns are becoming erratic, and with the conventional crops also failing to meet the demands of people for both food and feed (Chimwamurombe, 2008).

Genetic variability is a very basic asset for crop domestication and improvement, as well as for genetic research (Gepts, 2004). Marama bean has been found to display a very high intra-population diversity and a low inter-population diversity in several studies conducted over the past two decades and using several marker systems including the ribosomal deoxyribonucleic acid (rDNA) (Nepolo et al., 2010), simple sequence repeats/microsatellites (SSR) (Takundwa et al., 2010), random amplified polymorphic DNAs (RAPDs) (Naomab, 2004; Halloran and Monaghan, 1996), and amplified fragment length polymorphism (AFLP) markers (Naomab, 2004). However, relatively very low genetic diversity has been reported in certain populations, such as Omitara of Namibia (Nepolo et al., 2010).

Increasing crop yield to ensure food security is a very huge and important challenge world-wide (Azam-Ali, 1996). Plant breeding requires genetic variation of useful traits for crop improvement but yet and quite often, the desired variation is usually lacking (Ruane and Sonnino, 2006). Utagenic agents, such as radiation and certain chemicals, can be used to induce mutations and generate genetic variations from which desired mutants may be selected and developed (Dattaet al., 2009). Mutation induction has become a proven way of creating variation within crop varieties and mutagenesis is indeed an important tool in crop improvement and development, and is free of the regulatory restrictions commonly imposed on genetically modified (GM) organisms (Seetohul et al., 2009). This forward genetic approach enables the identification of improved or novel phenotypes that can be exploited in conventional breeding programmes (Parry et al., 2009).

Exploiting natural and/or induced genetic diversity is a proven strategy in the improvement of all major food crops, and the use of mutagenesis to create novel variation is particularly valuable in those crops with restricted genetic variability (Seetohul et al., 2009). Even though high intra-population diversity has been shown in marama bean, its natural populations are unfortunately still under very huge and immense pressure from both grazing and the human exploitation of its seed (Naomab, 2004; Chimwamurombe, 2010). Thus under this very delicate circumstance, it is therefore also very important and crucial to generate strategies for conserving and further developing the remaining wild germplasm of this very important and highly promising leguminous crop.

Whilst mutations occasionally occur spontaneously in nature, the frequency of such mutations is too low to be typically relied on, and particularly for the accelerated plant development and breeding systems. However, mutations induced by physical and chemical mutagens applicable to all plant and animal species can then be taken advantage of (van Harten, 2007). Mutations may

be major, such as large scale deletions of DNA, or relatively very minor and involve only point mutations. Mutation can be induced by irradiation with non-ionizing (for example, UV) or ionizing radiation (for example, X and gamma rays, alpha and beta rays, fast and slow neutrons). These physical mutagens often result in the larger scale deletion of DNA and changes in chromosomal structures (Girij and Dhanavel, 2009). By contrast, chemical mutagens most often only affect single nucleotide pairs (Parry et al., 2009). For plants, some of the most widely and commonly used mutagens include ethylmethane sulphonate (EMS), methylmethanesulphonate (MMS), hydrogen fluoride (HF), sodium azide, N-methyl-N-nitrosourea (MNU) and hydroxylamine (Netto et al., 2011).

Apparently, the degree of mutation is often dependent on the type of tissue and the level of mutagen exposure. Mutations at single nucleotide pairs are generally of the fact that transcriptomic analyses have since shown that large-scale plant mutagenesis may even induce greater changes in gene expression patterns than the transgene insertions (Batista et al., 2008).

The study presented here describes a molecular exploration on the potential usage of gamma radiation in the induction of useful and most preferable germplasm mutational changes of a wild African marama bean, for the possible adoption of this very important legume into modern domestication and its subsequent future participation in mutational and marker-assisted breeding programmes.

MATERIALS AND METHODS

Seed material and germination regimes

Seeds for this study were collected from a wild population of a Namibian marama bean plant, and the irradiation process was done by the International Atomic Energy Agency (IAEA) Laboratories in Vienna (Austria) prior to germination with normalization of seed moisture content. There were three experimental groups in this study: 50 seeds irradiated with 50 gamma rays (50Gy), 50 seeds irradiated with 100 gamma rays (100Gy), and 50 non-irradiated seeds (controls). For each experimental group, five batches of seeds in collections of 10 seeds per batch were surface-sterilized by transferring the 10 seeds into a sterile 50 mL Falcon tube followed by their flood-soaking with 10 mL 70% ethanol for 30 s. The seeds were then vortexed for 90 s and allowed to stand for another one and half minute. Ethanol was discarded and the seeds repeatedly washed (5 times) with sterile distilled water. The seeds were then submerged into 10 ml of sterilization buffer (50% bleach and 0.1% Triton X-100) and immediately vortexed for 3 to 5 min. The sterilization buffer was removed and seeds then thoroughly washed (5 times) with sterile distilled water. About 10 ml of 0.1% Type ‘M’ agar were then added to the washed seeds in the Falcon tube ensuring that all the seeds were fully submerged.

The tube was then incubated for 3 days at 4°C and in order to stratify the seeds for rapid and improved uniform germination rates. After stratification, the seeds were transferred to vials lined with sterile moist filter papers and then incubated (as is shown in Figure 1) for 14 days (the natural germination period of marama bean seeds) in a Plant Growth Chamber (Labex-LabconGC-300, Maraisburg, RSA) set at a constant temperature of 23°C, under an 18 h light and 6 h dark cycle. The time of emergence as well as the percentage germination of each of the three experimental groups were then evaluated and determined by respectively monitoring the exact time at which each of the various embryonic axes was produced as well as noting the exact number of embryonic axes that had successfully been produced by each group.

Extraction of total genomic DNA and its purification for polymerase chain reaction

The DNA material that was used for the molecular screening of any possible gamma ray-induced genetic mutations in the treated seeds was extracted from their emerging embryonic axes (Figure 2). Each embryonic axis coming out of a germinating seed was physically dissected with a sterile scalpel blade to expose its active mitotic tissue, and from which the genomic DNA was then extracted. This tissue (embryonic axis mitotic tissue), which includes the initial shoot and initial root of a new plant, has a very high DNA content to fresh weight ratio and thus the overall yield of DNA from this tissue is usually very excellent. In the study case, the targeted total genomic DNA was extracted using a Zymo Research Plant/Seed DNA Mini-prep kit and in accordance with the manufacturer’s instructions (Zymo Research Corporation, California, USA). The extracted DNA was then quantified using a Nanodrop 2000 spectrophotometer (Thermo Scientific, Maryland, USA), and also further resolved onto a 0.8% agarose gel stained with 1 µg/mL ethidium bromide in Tris-borate-EDTA (TBE) buffer and viewed under a UV illumination system (UV Transilluminator 2000, Bio-Rad Laboratories, Munich, Germany), before being used for the subsequent PCR amplifications.

Polymerase chain reaction

Out of screening 80 known primers for marama, MARA 0001-MARA080 for differences between irradiated and non-irradiated seeds, MARA 039 was found to detect differences. Polymerase chain reaction (PCR) amplifications were performed using a Thermo Scientific DreamTaq Green PCR Master mix (2X) (Thermo Scientific, Maryland, USA) in 25 µL reaction volumes using the following reconstitutions: 12.5 µL 2X DreamTaq Green PCR Master mix, 1.0 µL forward primer (MARA039: L-TCAATTAAAGGGCTCCATTGC), 1.0µL reverse primer (MARA039: R-ATGCCCAAATACCAACAAT), 8.5 µL sterile water and 2.0µL DNA template. The primer set (MARA039) specifically targeted and amplified the AGA repeat and microsatellite region of the extracted seed embryonic axis DNA. The PCR conditions on the thermocycler (C1000 Touch™, Bio-Rad Laboratories, Munich, Germany) were as follows: 1 cycle of Pre-denaturation: 95°C for 4 min; 35 cycles of Denaturation: 95°C for 30 s, Annealing: 55°C for 1 min, and Extension: 72°C for 2 min; 1 cycle of Final Extension: 72° for 5 min and a sample holding period at 4°C. The amplified PCR products were viewed on a 2% agarose gel in TBE buffer stained with 1 µg/mL.

Figure 2. Extraction of total genomic DNA from embryonic axes. The panel presents an embryonic axis emerging from a germinating seed. The total genomic DNA was subsequently extracted from the active mitotic region of this tissue.

ethidium bromide under UV illumination to check their sizes and qualities. The yielded amplicons were then cleaned up and concentrated for subsequent sequencing using a Zymo Research, DNA Clean and Concentrator-5kit (Zymo Research Corporation,
RESULTS

Emergence rates and percentage germinations

When comparing the non-irradiated (control) seeds and the irradiated (50 Gy and 100 Gy) seeds, both relatively higher emergence rates and percentage germinations were observed in irradiated seeds than in the non-irradiated seeds (Figure 3A and B). In terms of the emergence rates, the earliest time of embryonic axis emergence was observed in seeds treated with 100 Gy (3 days), followed by the seeds treated with 50 Gy (5 days) and then the control seeds (10 days). Once again, the highest number of seeds to germinate was observed in seeds treated with 100 Gy (92%), followed by the seeds treated with 50 Gy (76%) and then the control seeds (54%). This observation signifies a dosage-dependent inductive effect of the applied radiation that preferably favored both enhanced emergence rates and high percentage germinations.

Polymerase chain reaction

From the PCR work undertaken, the targeted and most desired AGA microsatellite repeat region of the marama
Figure 4. Electrophoresis gel of PCR products amplified in the AGA microsatellite repeat region of marama bean by the MARA039 primer set. The amplified products were resolved on a 2% agarose gel stained with 1µg/mL ethidium bromide and run in 1X TBE buffer at 90 V for 1 h. L is the 100 bp ladder, C represents the non-irradiated control seeds, 50Gy represents seeds irradiated with 50 gamma rays and 100Gy represents seeds irradiated with 100 gamma rays.

Figure 5. Sequence alignment of the amplified amplicons in the AGA microsatellite repeat region of marama bean. A MARA039 primer set was used to amplify various amplicon fragments of the AGA microsatellite repeat region of the marama bean seeds treated with either 0, 50 or 100 gamma rays. The amplified fragments were sequenced and then aligned in the Clustal X program in order to determine their specific point or AGA repeat mutations.

The bean plant was successfully amplified for both the irradiated and non-irradiated seeds (Figure 4). Amplifications were carried out using the MARA039 primer set (L-TCATTAAAGGCTCCATTGC; R-ATGCCCCAAAATCACCAACAT), which in all cases, succeeded to amplify the various amplicon fragments close in size to the expected for the marker 176 bp (Figure 4).

Sequence alignment

All obtained amplicons in Figure 4 were carefully excised and cleaned up for subsequent sequencing at the Inqaba Biotech, Pretoria, South Africa. Sequencing was undertaken in order to specifically determine the exact base pair differences between the various amplicons in the targeted microsatellite repeat region. The exact base pair differences were then determined by aligning the sequenced amplicons against each other in the Cluster X program and as is shown in Figure 5. Apparently, the targeted region of interest displayed several point mutations as well as some differences in the number of the AGA repeat units. All control samples retained their original 5 AGA repeat units and had no point mutations while the irradiated samples either gained or lost one to two more AGA repeat units and had several point mutations. This thus indicated that the irradiation system had some profound mutational effects of either changing the number or type of the AGA repeat units in the
targeted microsatellite region.

**BLAST searches**

After amplifying the AGA microsatellite repeat region in each of the irradiated or non-irradiated marama bean seeds and determining its irradiation-associated mutational changes, it was then necessary to attempt and establish the exact identity of this region in the marama bean plant. In order to achieve this, a BLAST search in the NCBI database using one of the non-irradiated amplicons was carried out. The search returned a 75% homologous hit which apparently was the non-catalytic beta sub-unit of a polygalacturonase (PG) enzyme in the *Medicago truncatula* genome (Figure 6). This then proposed that the targeted and amplified AGA microsatellite repeat region in the marama bean could also be the non-catalytic beta sub-unit of a polygalacturonase enzyme of this plant.

**DISCUSSION**

The study presented here describes how the process of gamma irradiation can be practically used as a method to induce detectable but agronomically important mutations in seeds of a wild trans-Kalahari legume, the marama bean (*T. esculentum*). After exposing the seeds to the various dosages of gamma rays (0, 50 and 100 Gy), the mutational effects of the applied radiation onto the exposed seeds were then studied by analyzing the molecular features of an AGA microsatellite repeat region that naturally exists in one specific area of the total genomic DNA of these seeds. Apparently, this particular area was specifically targeted for this study because its sequence-specific microsatellite primers (MARA039 set) have already been developed and the area can be easily amplified by polymerase chain reaction (PCR) (Takundwa et al., 2010).

When the MARA039 primer set was used to target and amplify the desired AGA microsatellite repeat region in the total genomic DNA of both the irradiated (50 Gy and 100 Gy) and non-irradiated (control) seeds, a number of amplicons were successfully amplified and all in the expected size range of between 100 and 200 bp (~176 bp) (Figure 4). A subsequent sequence alignment of those amplified fragments using Cluster X revealed that while DNA from all control seeds had maintained its original 5-AGA repeat, DNA from the irradiated seeds had either gained or lost one to two more AGA repeats (Figure 5), an aspect which typically suggested to us that the used irradiation system was practically capable of inducing some marginal genetic mutations into the exposed seeds. Furthermore, besides just altering the number of AGA repeat units, the irradiation system also could induce several point mutations in the exposed seeds (Figure 5). Apparently, when a single amplicon...
from the control seeds was used as a motif to BLAST search the NCBI database, it managed to return a single hit to which it had a 75% homologous similarity level, and this hit happened to be the non-catalytic beta sub-unit of a polygalacturonase (PG) enzyme from Medicago truncatula (Figure 6). This then thus proposed to us that the targeted and amplified AGA microsatellite repeat region in the marama bean could also be the non-catalytic beta sub-unit of a polygalacturonase enzyme of this plant.

In the plant family, polygalacturonases (PGs) are a group of enzymes which chiefly degrade cell wall pectin compounds (Swain et al., 2011) by primarily hydrolyzing the α-1,4 glycoside bonds that naturally exist between two residues of galacturonic acid in the pectin chain (Swain et al., 2011; Ghianiet al., 2011). PGs are always strongly associated with the various and very important plant developmental processes such as seed germination (Kanai et al., 2010), pollen tube growth (Clarke and Gleeson, 1981; Mu et al., 1994), fruit maturation (Ghianiet al., 2011), lateral root outgrowth (Peretto et al., 1992), organ abscission (Taylor et al., 1990; Bonghi et al., 1992), seed pod dehiscence (Jenkins et al., 1996), and the intrusive growth of non-articulated laticifers (Wilson et al., 1976). In the process of seed germination, the hydration of a seed by water usually results in increased metabolic activities, which either stimulate the synthesis of new enzymes or literally enhance the activation of pre-existing ones, with the mobilization of reserves and digestion of the cell wall, weakening it and causing a consequent rupture of the integument by the radicle (Baskin and Baskin, 1998). Typically, the developing radicle always requires a weakening of the endosperm tissue opposite its tip (Clarke and Gleeson, 1981; Mu et al., 1994) as well as a softening of the integument for its successful protrusion (Baskin and Baskin, 1998; Kanai et al., 2010) and consequently, both processes are primarily controlled by PGs (Karssen et al., 1989).

Now considering the proposed possible link between the AGA microsatellite repeat region and the non-catalytic beta sub-unit of the polygalacturonase gene in the marama bean, it was therefore not unusual for us to speculate for some possible phenotypic changes in the germination profiles of those seeds whose microsatellite regions had been altered by exposure to the applied gamma irradiation. Not surprisingly, all irradiated seeds somewhat showed some relatively high emergence rates (Figure 3A) as well as some relatively enhanced germination percentages (Figures 3B) when compared to their non-irradiated counterparts, and thus suggesting to us for a possible induction of some relatively positive and somewhat favorable mutational effects onto the exposed seeds by the applied gamma irradiation, which eventually improved their emergence and germination efficiencies.

In this regard, it appears as though that the generated and acquired mutational changes (both the repeat unit changes and point mutations) in the microsatellite repeat region of the marama bean seeds could have had favored some conformational and structural changes in the non-catalytic domain of the polygalacturonase gene that then eventually enhanced the catalytic activity of this enzyme and finally resulting in improved emergence and germination profiles of the irradiated seeds.

By summing up all these findings, it is conceivable to state that the process of gamma irradiation can be potentially used as a practical method in both the marker-assisted and mutation breeding programs of the marama bean for its ultimate improvement as an indigenous legume of the Kalahari regions of Africa. Notably, the fact that the observed induced mutations tended to target the microsatellite region, MARA 039, which seems to be part of an enzyme with central roles in various important plant developmental processes, typically makes this suggestion an imminent possibility. Apparently and in some previous domestication efforts of the marama bean, researchers have frantically been trying to search for ways to reduce the seed cycle of this legume, which apparently appears to be not less than 18 months (unpublished data) but to no success. However, and based onto this study findings here, the approach of mutational breeding may be a possible option to attempt and reduce this lag period by producing new mutants with early and improved germination efficiencies.

Furthermore, the fact that the PG enzyme is also primarily involved in earlier fruit maturation means that its potential modification to favor both the early seed germination and early fruit maturation would strongly augment the practical shortening of its seed cycle in the developed marama bean mutants and probably making this wild legume an ideal candidate for possible domestication and becoming one of the mainstream crops for the Kalahari regions of Africa.

Conclusion

Plant breeding has evolved and is no longer limited to simple selection, but is also concerned with the creation, selection, evaluation and multiplication of desirable genotypes. Apparently, the process of mutagenic breeding can now be shortened by new techniques such as in vitro culture, molecular markers as well as the use of mutagenesis to increase the genetic variability of plants. The mutation breeding technique has led to the recent significant increase in cultivars released and applying it to emerging crops like the marama bean will eventually benefit its production. Thus based on findings of this study, the use of gamma irradiation in the marama bean...
for the induction of various favorable mutations seems a very feasible approach that will result in the generation and establishment of mutants with very important and most desirable agronomic traits such as early seed germination and early fruit maturation.

Conflict of Interests

The authors have not declared any conflict of interests.
