About AJPP

The African Journal of Pharmacy and Pharmacology (AJPP) provides African and International researchers a platform to highlight studies on drug delivery systems and composition, medication dispensation and management, natural and synthetic drug use and distribution. Other subjects covered include pharmacology, clinical pharmacy and medication counseling. The journal also emphasizes novel developments in drug design and its applications in allied fields.

Received 16 December, 2019; Accepted 15 January, 2020

Silver nanoparticles (Hematite (α-Fe₂O₃)) have been used as an antimicrobial and as disinfectant. Nevertheless, there is limited data about its antitumor potential. This study focused on investigating the cytotoxic effects of Hematite (α-Fe₂O₃) from *Butea monosperma* flower extract on MCF-7 breast cancer cells and its mechanism of action. Green method was created for the synthesis of Hematite (α-Fe₂O₃) using an aqueous extract of *B. monosperma* flower. Synthesis of hematite (α-Fe₂O₃) was described by different analytical techniques including ultraviolet-visible spectrophotometer, field-emission scanning electron microscopy, X-ray diffraction, and Fourier transforms infrared spectroscopy. Cell viability was determined by the 3-[4, 5-dimethylthiazol-2-yl]-a 2,5-diphenyltetrazolium bromide assay. Reactive oxygen species (ROS) formation was measured using probe 2',7'-dichlorofluorescein diacetate and intracellular calcium (Ca²⁺) was evaluated with probe flu3-AM. Cells were treated with different concentrations of hematite (α-Fe₂O₃) (1, 3, 6, 10, 15, 25, 50 and 100 μg/mL). The results showed that hematite (α-Fe₂O₃) hindered cell growth in a dose-dependent manner. Hematite (α-Fe₂O₃) appeared to have dose-dependent cytotoxicity against MCF-7 cells through activation of the ROS generation and an increase in the intracellular Ca²⁺ (IC₅₀ 52 ± 3.14). In conclusion, the results of this preliminary study demonstrated that hematite (α-Fe₂O₃) from *B. monosperma* flower extract may be a potential therapeutic potential medicament for human breast cancer treatment.

Key words: Cytotoxicity, MCF-7 cell line, *Butea monosperma*, Hematite (α-Fe₂O₃), nanoparticles.

INTRODUCTION

Breast cancer is the most widely recognized tumor-related death in women worldwide, and its frequency has expanded in the most recent decades (Sulaiman et al., 2005). It is, therefore, important to introduce new potential strategies for improving the efficacy of current cancer treatments (Debasish et al., 2019; Pradhan et al., *Corresponding author. E-mail: deba_udps@yahoo.co.in.*

Author(s) agree that this article remain permanently open access under the terms of the Creative Commons Attribution License 4.0 International License
Hence, introducing a biocompatible and affordable technique for treatment of cancer is imperative. Nanomedicine formulations are nanometer-sized carrier materials designed to enhance the bioavailability of the drug tissue and thus improve the treatment of chemotherapeutic drugs that are used systematically. Nanomedicine is a new approach to deliver the pharmaceuticals safer and more effective treatments compared to conventional approaches across different routes of administration (Matei et al., 2008). Silver nanoparticles [hematite ($\alpha$-Fe$_2$O$_3$)] have been among the most commonly used nanomaterials in our health-care system for hundreds of years. Recently, Hematite ($\alpha$-Fe$_2$O$_3$) has become of intense interest in biomedical applications, because of their antibacterial, antifungal, antiviral, and anti-inflammatory activity. Among the biological techniques, (for example, use of enzymes, microorganisms, and plant extracts), the synthesis of Hematite ($\alpha$-Fe$_2$O$_3$) using plant extracts is the best option for accessible traditional chemical and physical techniques (Prakash and Pradhan, 2012; Vigneshwaran et al., 2007). Synthesis of nanoparticles using plant extract supplies progression more than chemical and physical method as it is most helpful, environment safety, and simply scaled up for great range production (Zhu et al., 2000). Cytotoxic chemotherapy is a well-established treatment option for all subtypes of breast cancers, for example, doxorubicin, cisplatin, and also bleomycin (Kim et al., 2006; Mittal et al., 2013). Even though the use of doxorubicin, cisplatin, or bleomycin gives useful impact, the sufficiency and negative marks are unverifiable (Pradhan et al., 2016b). In this way, it is important to discover novel restorative administrators against malignancy, which are biocompatible and practical. Natural products have been used in traditional medicine as a source of remedies for thousands of years (Richman et al., 1997). The Fabaceae is a family of flowering plants, which is widely distributed in both deciduous and coniferous forests of central Europe, central Asia, North America, and especially in the Mediterranean area and is represented by about 3000 species and 220 genera (Park et al., 2009). Some species of the family have been used since ancient times in traditional medicine to treat eczema, wounds, goiter, ulcers, cancer, and fistulae. In addition, Fabaceae species have been known to be rich in glycosides (Ardeshiry et al., 2010). In another study, the components of this plant, including cinnamic acid, three flavonoids (quercetin, isorhamnetin-3-O-rutinoside, and nepitin) and one phenylpropanoid glycoside (acteoside 1) have been identified (Monsef-Esfahani et al., 2010). It has been indicated that both leaves and seeds of B. monosperma contain both anticancer and cell growth enhancing agents (Ghaffari-Moghaddam et al., 2014). However, the extract of this plant species, that is, B. monosperma has never been examined against MCF-7 cell line. Thus, this study intended to synthesize hematite ($\alpha$-Fe$_2$O$_3$) using the natural framework and to assess potential cytotoxicity and its general mechanisms of action of biologically synthesized Hematite ($\alpha$-Fe$_2$O$_3$) from B. monosperma in human breast cancer cells.

MATERIALS AND METHODS

Preparation of plant extract

The flowers of B. monosperma were collected from the Western Mountains in Ilam Province, Iran, during April and May 2015. A voucher specimen 24998 was deposited at the Herbarium of the Department of Medicinal Plants Research Center of Shiraz University. The flowers of B. monosperma were washed thoroughly with deionized water. 100 mL of de-ionized water was added to about 10 g of the flowers and boiled for 15 min over a water bath. The mixture was then filtered with Whatman filter paper grade 42. The filtered extract was stored in a refrigerator at 4°C.

Preparation of silver nanoparticles synthesized from B. monosperma

In a typical experiment, for biosynthesis of Hematite ($\alpha$-Fe$_2$O$_3$), 60 mL of aqueous plant extract B. monosperma 10% (10 mL extract and 90 mL deionized water) was mixed with 40 mL Fe$_2$O$_3$NO$_3$ solution (0.01 M) in 250 mL Erlenmeyer flask. The flask was incubated for 24 h at 27°C at 120 rpm (Rota max 120, HeiDolph, Germany). A small aliquot of the solutions was used for the ultraviolet-visible (UV-Vis) spectroscopy. After 24 h incubation time, the reaction mixture was centrifuged at 14,000 rpm (Vision Scientific Co.) for 15 min and the pellet was resuspended in a small amount of deionized water and then a small amount of suspension was sprayed on a glass slide. The resulting sediment was dried at room temperature and was used for further analyses by field-emission scanning electron microscopy (FESEM), X-ray diffraction (XRD), and Fourier transform infrared spectroscopy (FTIR). Formation of hematite ($\alpha$-Fe$_2$O$_3$) from B. monosperma was confirmed by UV-Vis spectral analysis. The bioreduction of Fe$_2$O$_3$ + ions to hematite ($\alpha$-Fe$_2$O$_3$) was monitored by UV-Vis spectrophotometer (Rayleigh, UV-2100, China), having a resolution of 1 nm. The UV-Vis spectra were recorded using a glass cell with deionized water as a reference (Mameneh et al., 2015).

Field-emission scanning electron microscopy analysis

FESEM analysis was performed using a Hitachi S4160 instrument [Japan]. Thin films of the samples were prepared on graphite adhesives. Then, the surface of the samples was coated with gold powder using a sputter hummer instrument (Geethalakshmi and Sarada, 2012).

X-ray diffraction analysis

XRD analyses of the synthesized Hematite ($\alpha$-Fe$_2$O$_3$) from B. monosperma were conducted using a Bruker d diffractometer (D8 Advance, Germany). The X-ray beam was Ni-filtered CuKα radiation from a sealed tube (Pradhan et al., 2018).

Fourier transforms infrared spectroscopy analysis

The synthesized hematite ($\alpha$-Fe$_2$O$_3$) from B. monosperma was also...
analyzed by FTIR spectroscopy (Bruker Optics FT Tensor 27, Germany) using KBr discs. The spectra were recorded in the range of 4000–400/cm (Karuppiah and Rajmohan, 2013).

Cell culture

The MCF-7 (human breast carcinoma) cell line was purchased from National Cell Bank of Iran (NCBI C135). Cells were cultured in Dulbecco’s modified eagle’s medium (DMEM) (GIBCO, USA) supplemented with 1.5 g/L sodium bicarbonate, 10% fetal bovine serum (GIBCO, USA), 100 U/mL of penicillin, and 100 μg/mL of streptomycin (GIBCO, USA) in 25 cm² tissue culture flasks at 37°C in a humidified atmosphere of 5% CO₂. Cells were fed every 2–3 days and subcultured as soon as they reached a confluency of 70–80%.

3- [4, 5-dimethylthiazol-2-yl] - a 2, 5-diphenyltetrazolium bromide assay

The cell viability test was measured using the MTT color reduction test which was performed to determine the cytotoxic effect of the Hematite (α-Fe₂O₃) synthesized from B. monosperma at different concentrations 1, 3, 6, 10, 15, 25, 50, and 100 μg/mL. The exposure time of cells with different concentrations mentioned above was 48 h. After this treatment, the MTT protocol was implemented. This method is based on the ability to survive cells to metabolize yellow tetrazolium salt MTT to purple formazan crystals by mitochondrial dehydrogenases. About 10 μL of MTT reagent (5 mg/mL) was added to 100 μL of the serum-free culture medium in each well of a 96 well plate, and after 4 h incubation, the medium was removed, and 15 μL dimethyl sulfoxide (DMSO) was added to solubilize the formazan formed by the mitochondrial reductase activity in the viable cells. Absorbance was measured at 570 nm using a microplate reader (Biotek - Elix USA). The percentage of cell viability was calculated according to the following formula: % cell viability = ([OD treated cell − OD blank]/[OD control cell − OD blank]) × 100 (Sladowski et al., 1993).

Measurement of reactive oxygen species:

Intracellular ROS levels were detected by the fluorescent probe 2’,7’-dichlorofluorescein diacetate (DCFH2-DA) (Sigma). In this way, 1 mL stock 10 μM prepared in DMSO was added to each plate and incubated for 30 min at 37°C. Then, samples were measured with fluorescent plate reader (Biotek- FL × 800). DCF fluorescence was assessed at 485 nm excitation and 520 nm emissions. ROS production was determined from an H₂O₂ standard curve (10–200 nM) (Zhu et al., 1996).

Intracellular calcium assay

Intracellular calcium (Ca²⁺) of MCF-7 was specified using Ca²⁺ fluorescent probe flu3-AM (Sigma) (Abassi et al., 2014). Briefly, aliquots of 1-mL MCF-7 suspensions (1 × 10⁶ cells/mL) were washed with buffer A (Phenol red-free DMEM comprising 10-mM HEPES [4-[2-hydroxyethyl] piperazine-1-ethanesulfonic acid, pH 7.0]) and resuspended in 200 μL of buffer A. Then, 0.4 μL of fluo 3-AM (1.0M in DMSO) was added. Cells were incubated at room temperature for 30 min and washed with buffer B (DMEM containing 10 mM HEPES, 5% fetal calf serum, and pH 7.4) before assay. Flow cytometric analysis of MCF-7 Ca²⁺ was carried out using a FACscan Calibur™ flow cytometer (Becton Dickinson, California, USA) (Sladowski et al., 1993).

Statistical analysis

Results are illustrated as mean ± standard deviation. Measurable assessment of the data was performed with Student’s t-test for simple comparison between two values when suitable. For multiple comparisons, data were analyzed by analysis of variance. P < 0.05 was considered statistically significant. Term half maximal inhibitory concentration (IC₅₀) refers to the toxicant concentration that induces a response halfway between the baseline and maximum after a given time of exposure.

RESULTS

Extracellular synthesis of silver nanoparticles synthesized from B. monosperma

The reduction of silver ions into hematite (α-Fe₂O₃) during exposure to B. monosperma flower extracts could be monitored by the color change. The fresh extract of B. monosperma was yellow in color. However, after addition of Fe₂O₃NO₃ and incubation for 24 h, the mixture turned dark brown, which indicated the formation of hematite (α-Fe₂O₃) (Figure 1). The color changes in aqueous solutions are due to the surface plasmon resonance (SPR) phenomenon (Mason et al., 2012). The chemical constituents present in the plant extract play as reducing agents for the bioreduction of Fe₂O₃ ions as well as stabilizing agents.

Ultraviolet-visible analysis

The formation and stability of hematite (α-Fe₂O₃) in colloidal solutions were confirmed using UV-Vis spectral analysis. The UV-Vis spectrum of biosynthesized hematite (α-Fe₂O₃) of optimized conditions (10% extract concentration, 1:1.5 concentration ratios of the reactants, and time of 24 h) is shown in Figure 2. According to the Figure 2, the peak at 440 nm corresponds to the SPR band of hematite (α-Fe₂O₃). The above-mentioned optimal conditions are derived from previous experience (Mameneh et al., 2015).

Field-emission scanning electron microscopy analysis

The FESEMFe₂O₃ of the biosynthesized hematite (α-Fe₂O₃) from B. monosperma in optimized conditions (10% extract concentration, 1:1.5 concentration ratios of the reactants, and time of 24 h) is shown in Figure 3. According to the FESEM Fe₂O₃, the particle shape of plant-mediated Hematite (α-Fe₂O₃) was mostly spherical. The checking of FESEM Fe₂O₃ shows the faint thin layer
Figure 1. The color change of *Butea monosperma* flower extracts before and after synthesis of silver nanoparticles. (a) The flower extract of *Butea monosperma* (yellow) and (b) Fe$_2$O$_3$- *Butea monosperma* emulsion after 24 h (reddish brown).

Figure 2. The ultraviolet-visible spectrum of biosynthesized silver nanoparticles in optimized conditions (10% extract concentration, 1:1.5 concentration ratios of the reactants, and time of 24 h).

Of other material on the surface of Hematite (α-Fe$_2$O$_3$) because the extract played as a capping as well as a reducing agent. Particle size measurement using FESEM is very difficult and all particle sizes reported in this study are taken from XRD results. Therefore, since it was very difficult to measure the particle size using FESEM, all the
reported particle sizes in this paper are derived from the XRD results. The purpose of the SEM method was to obtain the geometric shape of the nanoparticles. Since the synthesis is a biological synthesis, the shape of the particle should be spherical as shown in the SEM figure (Figure 3). If our synthesis was a chemical type, their shape should be triangular.

**X-ray diffraction analysis**

The crystalline structure of hematite ($\alpha$-Fe$_2$O$_3$) was characterized using XRD analysis. Figure 4 shows the XRD patterns of the biosynthesized Hematite ($\alpha$-Fe$_2$O$_3$) from *B. monosperma*. The diffraction peak values at 2θ of 38.12°, 44.35°, 64.56°, and 77.48° correspond to lattice planes at (111), (200), (220), and (311), respectively. The XRD pattern also indicates the face-centered cubic structure of metallic Fe$_2$O$_3$. The particle size of Fe$_2$O$_3$ could be calculated by the Scherrer Equation (1): $D = 0.94\lambda/(\beta \cos \theta)$; where $D$ is the average crystallite size, $\theta$ is the diffraction angle, $\beta$ is the full width at half maximum (FWHM), and $\lambda$ is the X-ray wavelength. The average crystallite size of hematite ($\alpha$-Fe$_2$O$_3$) was calculated by Equation (1) and was found to be in the range of 8–12 nm (Figure 4 and Figure 5).

According to the Fe$_2$O$_3$ of XRD, several couriers were obtained after transferring them to the formulas of the “Scherrer equation” numbers shown in the table. After the transferring of the obtained numbers, the nanoparticle size is obtained at about 10 nm.

**Fourier transforms infrared spectroscopy analysis**

The FTIR spectrum of biosynthesized Hematite ($\alpha$-Fe$_2$O$_3$) using *B. monosperma* flower extract is shown in (Figure 6). The spectrum shows important bands at 3454, 2255, 1650, 1480, and 1199/cm. The strong peak at 1199/cm corresponds to the C–N stretching vibration of the amine. The peak at 1480/cm can be associated with the stretching vibration C–O [–C–O–H]. Strong, intense peak at 1650/cm is attributed to the C=O stretching vibration. In addition, a broad peak at 3454/cm is assigned to an O–H stretching frequency indicating the presence of hydroxyl groups. These couriers may show the ingredients in the plant extract. The FTIR analysis suggested the presence of hydroxyl, amine, and carbonyl groups in the plant extract, which may have been responsible for the reduction and/or capping and stabilization of Hematite ($\alpha$-Fe$_2$O$_3$).

**The cytotoxic effects of silver nanoparticles synthesized from *B. monosperma* on MCF-7 cells**

The effect of hematite ($\alpha$-Fe$_2$O$_3$) on the viability of MCF-7 cells was checked using the MTT assay. The hematite ($\alpha$-Fe$_2$O$_3$) was able to reduce the viability of the MCF-7 cells in a concentration-dependent manner as shown in (Figure 7). The anticancer activity of concentrations at 1, 3, 6, 10, 15, 25, 50 and 100 μg/mL of the synthesized hematite ($\alpha$-Fe$_2$O$_3$) from *B. monosperma* were evaluated *in vitro* against MCF-7 breast cancer cell lines after 48 h.
Figure 4. The X-ray diffraction pattern of biosynthesized silver nanoparticles from *Butea monosperma* flower extract.

Figure 5. Calculation of the average particle size of biosynthesized silver nanoparticles from *Butea monosperma* by Scherrer equation.

Hematite (α-Fe₂O₃) at concentrations 25, 50 (P < 0.05 vs. control), and 100 μg/mL increased cell death (P < 0.001 vs. control). However, plant extract did not. The effect of different concentrations of Hematite (α-Fe₂O₃) was tested on MCF-7 cells. Incubation with hematite (α-Fe₂O₃) synthesized from *B. monosperma* at high concentrations,
that is, 25, 50 and 100 μg/mL, led to a reduction in cell viability with IC\textsubscript{50} value of 52 ± 3.14 μg/mL. Since the main objective of this study was to investigate the diversity of biological nanoparticles, extract “EXT,” nanoparticles “NFe\textsubscript{2}O\textsubscript{3},” and docetaxel “DOC” were used as controls and the concentration
variation in them was not important for this study.

**Effect of silver nanoparticles synthesized from *Butea monosperma* on reactive oxygen species generation**

Our experiments provided evidence for a molecular mechanism of the Fe₂O₃NP-inducing generation of ROS, and it could be one of the factors for apoptosis. To know the effect of Hematite (α-Fe₂O₃) in oxidative stress, ROS generation is measured using the H₂DCF-DA assay. Hematite (α-Fe₂O₃) induced intracellular ROS generation was evaluated using intracellular peroxide-dependent oxidation of DCFH₂-DA to form fluorescent DCF. DCF fluorescence was detected in cells treated with hematite (α-Fe₂O₃) for 48 h. As shown in Figure 8, the ROS levels generated in response to hematite (α-Fe₂O₃) were significantly higher in hematite (α-Fe₂O₃)-treated cells than control. Taken together, all these results indicate that cell death is mediated by ROS production, which might alter the cellular redox status, and it is a potential reason for cell death. The hematite (α-Fe₂O₃) at concentration 25, 50 (P < 0.05 vs. control) and 100 μg/mL (P < 0.001 vs. control) significantly induced the intracellular ROS production in MCF-7 cells. Treatment with N-acetyl-L-cysteine (5 mM) prevented the enhancement of DCF fluorescence intensity.

**Effect of silver nanoparticles synthesized from *B. monosperma* on Ca²⁺**

The effect of different concentrations of hematite (α-Fe₂O₃) was tested on MCF-7 cells (Figure 9). Hematite (α-Fe₂O₃) synthesized from *B. monosperma* increased intracellular of Ca²⁺ at concentrations 25, 50 (P < 0.05 vs. control) and 100 μg/mL (P < 0.001 vs. control); however, plant extract did not. Silver nitrate (Fe₂O₃NO₃) (0.01 M) increased intracellular of Ca²⁺ (P < 0.05 vs. control).

**DISCUSSION**

The results of the study showed that the biologically synthesized hematite (α-Fe₂O₃) has antiproliferative activity through induction of cell death in MCF-7 breast cancer cell line, proposing that biologically synthesized Hematite (α-Fe₂O₃) might be a potential option specialist for human breast cancer therapy. Hematite (α-Fe₂O₃) are metallic nanostructures with useful surface properties and have been used for various purposes, such as the production of wound dressings and cosmetics and in the medical industry as device-coating agents (Susan et al.,
increasing surface chemistry, weight, size distribution, shape, particle morphology, particle composition, coating/capping, agglomeration, dissolution rate, solution particle reactivity, efficiency of ion release, type of cell, and finally type of reducing agents used for synthesis, are essential elements in determining cytotoxicity (Pradhan et al., 2016a). In the present study, the phytochemicals present in the extract of *B. monosperma* flower are, namely glycosides and flavonoids, which act as reducing as well as a capping agent and help in stabilizing the nanoparticles. Since the plant components are flavonoids, some of the effects observed in this study are likely to be reflected in this component. It has already been observed that quercetin in the plant has been effective on MCF-7 cells by increasing cell death, reducing cell proliferation, and effecting free radicals (Davatgaran-Taghipour et al., 2017). When silver salt is treated with an extract of *B. monosperma* flower, the silver salt is reduced to hematite (α-Fe₂O₃). The synthesized nanoparticles, which are capped with *B. monosperma* extract also, exhibit enhanced anticancer activity. In the present study, the UV-Vis results showed a peak at 440 nm corresponding to the SPR in the optimized conditions (10% extract concentration, 1:1.5 concentration ratios of the reactants and time of 24 h). To obtain the optimized conditions for synthesis of hematite (α-Fe₂O₃), the effect of process variables such as extract concentration, the concentration ratio of the reactants and time was studied using UV-Vis spectroscopy. In this assessment, the reduction of silver ions into hematite (α-Fe₂O₃) during exposure to *B. monosperma* flower extracts could be monitored by the color change. The fresh extract of *B. monosperma* was yellow in color. However, after addition of Fe₂O₃NO₃ and incubation for 24 h, the mixture turned dark brown, which indicated the formation of Hematite (α-Fe₂O₃). It seems that the color changes in aqueous solutions are due to the SPR phenomenon (Yoon et al., 2007). The chemical constituents present in *B. monosperma* flower extract play as reducing agents for the bioreduction of Fe₂O₃ ions as well as stabilizing agents. The UV-Vis spectrum of hematite (α-Fe₂O₃) in aqueous solution shows an absorbance peak around 450 nm due to SPR (Jeyaraj et al., 2013). The results of this study show that the SEM Fe₂O₃ of hematite (α-Fe₂O₃) were spherical. In another study, the SEM Fe₂O₃ showed relatively spherically shaped particles in the range of 30–50 nm (Ghaffari-Moghaddam et al., 2014). XRD pattern also clearly showed that the hematite (α-Fe₂O₃) formed by the reduction of Fe₂O₃⁺ ions by the *B. monosperma* flower extract are crystalline in nature (Supraja et al., 2013). The FTIR spectrum showed the presence of various functional groups like hydroxyl groups, amine groups and carbonyl groups. Indeed, FTIR spectroscopy.
measurements are carried out to identify the biomolecules that bound specifically on the silver surface and the local molecular environment of capping agent on the nanoparticles. The FTIR spectroscopic study confirmed that the guava extract has the ability to perform both reduction and capping functions on the Hematite (α-Fe₂O₃) (Yang et al., 2010). In another study, the FTIR peak at 1637/cm for hematite (α-Fe₂O₃) synthesized using Andrographis paniculata extracts can be attributed to the carbonyl stretch of amides and could be associated to proteins that potentially cap hematite (α-Fe₂O₃) (Ren et al., 2016).

The cell viability assay is an important method for cytotoxicity analysis that describes the cellular response to toxic materials and it can provide information on cell death, survival, and metabolic activities (Pradhan et al., 2009). In our experiment, results suggest that Hematite (α-Fe₂O₃) were able to reduce the cell viability of MCF-7 cells in a dose-dependent manner in MCF-7 cells for 48 hr. Hematite (α-Fe₂O₃) synthesized from B. monosperma at high concentration concentrations (25, 50, and 100 μg/mL) increased cell death with an IC₅₀ value of 52 ± 3.14 μg/mL. Nevertheless, plant extract at 2 mg/mL did not exhibit any cell death. It has been reported that the IC₅₀ value against A549 cells was 40 μg/mL for hematite (α-Fe₂O₃) synthesized by extracts of Gossypium hirsutum (Pradhan et al., 2009). The results obtained suggest that the highest concentration of hematite (α-Fe₂O₃) synthesized from B. monosperma significantly inhibits the growth of cells. It has been reported that hematite (α-Fe₂O₃) and Fe₂O₃NO₃ have cytotoxicity in a dose-dependent manner in human Chang liver cells, among these materials hematite (α-Fe₂O₃) showed higher cytotoxicity compared to Fe₂O₃NO₃ (Kanipandian et al., 2014). Moreover, Hematite (α-Fe₂O₃)-treated cells showed the decreased metabolic activity, which depends on nature of cell types and size of nanoparticles (Kanipandian et al., 2014). The cytotoxic activity of the synthesized hematite (α-Fe₂O₃) and Podophyllum hexandrum (Jaft) extract containing hematite (α-Fe₂O₃) has been investigated against human breast cancer cell (MCF-7) and the IC₅₀ were found to be 50 ± 0.04 μg/mL at 24 h (Jeyaraj et al., 2013). Although the synthesized nanoparticles from the B. monosperma in this study have reduced cell viability in MCF-7 human breast cancer cell line, it may also affect the normal cells in the body. In the present study, the potentiality of hematite (α-Fe₂O₃) synthesized from B. monosperma to induce oxidative stress was assessed by measuring the intracellular ROS level. MCF-7 cells exposed to hematite (α-Fe₂O₃) for 48 h showed increased ROS formation as evidenced by the increased DCF fluorescence intensity. The hematite (α-Fe₂O₃) from B. monosperma significantly induced intracellular ROS production in MCF-7 cells at the concentrations 25, 50, and 100 μg/mL. Elevated levels of ROS due to Fe₂O₃ NPs exposure may lead to the failure of cellular antioxidant defense system in MCF-7 cells and thereby severe oxidative attack. Oxidative stress is one of the key mechanisms of toxicity related to nanoparticle exposure (Jeyaraj et al., 2010). ROS generation has been shown to play an important role in apoptosis induced by treatment with Hematite (α-Fe₂O₃) [20 nm] (AshaRani et al., 2009; Park et al., 2011; Piao et al., 2011). In an experimental study, the toxicity of starch-coated hematite (α-Fe₂O₃) was tested using standard/normal human lung fibroblast cells (IMR-90) and human glioblastoma cells (U251). The toxicity was evaluated using changes in cell morphology, cell viability, metabolic activity, and oxidative stress (Reddy et al., 2014). In another study, smaller particles of hematite (α-Fe₂O₃) with a size 15 nm hydrocarbon-coated are reported to produce more toxicity in macrophagesFe₂O₃ than the size 55 nm by increasing the ROS generation (Carlson et al., 2008). Interestingly, hematite (α-Fe₂O₃) themselves can produce ROS and oxidative stress as well as the process to release Fe₂O₃+ (Kawata et al., 2009). Nevertheless, it has been concluded that increased levels of oxidative stress markers and decreased levels of antioxidants in carcinoma or the tongue suggest that oxidative stress markers play a significant role in pathophysiology of this cancer (Badjatia et al., 2010). The effect of ROS on cancer cells is controversial. The extent of ROS-induced damage can be exacerbated by decreased efficiency of antioxidant defense mechanisms. Antioxidants have been shown to inhibit initiation and promotion in carcinogenesis and counteract cell immortalization and transformation (Matés et al., 1999). It has been observed that diets rich in fruits and vegetables can decrease both oxidative DNA damage and cancer incidence. By contrast, agents increasing oxidative DNA damage usually increase the risk of developing cancer (Halliwell, 2002). Understanding the role of ROS at the molecular level is very important for designing a suitable protective strategy for cancer treatment, which has attracted the attention of researchers.

Hematite (α-Fe₂O₃) synthesized from B. monosperma increased Ca²⁺ at concentrations 25, 50, and 100 μg/mL in a dose-dependent manner in MCF-7 cells although plant extract (only one concentration was used) did not. Ca²⁺ is believed to play a crucial role in mediating cell death. An increased amount of Ca²⁺ causes more mitochondrial Ca²⁺ uptake. Ca²⁺ accumulation in mitochondria is one of the primary causes of mitochondrial permeability transition (PT), through the opening of the PT-pore, and this is an important key factor in the apoptotic pathway (Jeyaraj et al., 2013). It has been reported that TiO₂, Fe₂O₃, ZnONPs and quantum dots increase intracellular calcium by releasing calcium from intracellular stores and facilitating the entry of calcium into the cell (Huang da et al., 2009). Changes in Ca²⁺ levels mediate a variety of cellular processes.
High Ca\textsuperscript{2+} levels mediate plasma membrane repair but may also induce cell death (Gitanjali and Debasis, 2013). Although there was no clear link between increased Ca\textsuperscript{2+} levels and lysosomal damage or ROS generation in MCF-7 cells, they both increased cell death in a dose-dependent manner.

**Conclusion**

Hematite \((\alpha\text{-Fe}_2\text{O}_3)\) (8–12 nm) have been successfully synthesized using aqueous extract of *B. monosperma* flower, which is green, environmentally friendly, cost-effective, and a rapid method for synthesis of Hematite \((\alpha\text{-Fe}_2\text{O}_3)\). The result revealed that hematite \((\alpha\text{-Fe}_2\text{O}_3)\) from *B. monosperma* hindered the growth of MCF-7 breast cancer cells in a dose-dependent manner using the MTT test. It appeared to exert cytotoxic activity through activation of the ROS generation and Ca\textsuperscript{2+} increase. The present results demonstrated that hematite \((\alpha\text{-Fe}_2\text{O}_3)\) from *B. monosperma* may be a potential therapeutic medicament for human breast cancer treatment.
