Yield and quality of dual-purpose barley and triticale in a semi-arid environment in Tunisia

Sadreddine BEJI

Forage Crops Department, Higher Institute of Agriculture Kef, Boulifa 7119, Kef, Tunisia.

Received 12 January, 2016; Accepted 20 July, 2016

The semi-arid region of Tunisia is characterized by a low and erratic rainfall. This makes year-round maintenance of pasture and forage production under non-irrigated conditions both costly and difficult. In order to fill the winter feed gap in the livestock cycle; some cereals can be used as dual-purpose. This study aimed at evaluating agronomic performances and grain quality of two dual-purposes cereal crops, Barley and Triticale, cut at the pseudo stem erect stage (C30). The trial was conducted during 2010-2011 and 2011-2012 seasons under a semi-arid environment. Yields did not significantly differ between years and although barley yielded more forage crop than triticale the yield was not significantly different. Crude protein in the plant was significantly higher in barley (18.2%) compared to triticale (17.4%). Defoliation has caused a significant grain yield reduction for both cereals and was about 22% for triticale and 28% for barley; grain yield after forage removal was statistically higher for triticale (3.47 T/ha) than barley (2.85 T/ha). As average for the two seasons of the trial, grain protein was significantly higher after clipping for barley (11.35% for dual purpose and 10.17% for grain production only) and was not affected for triticale (9.38% versus 9.55%). Under Tunisian semi-arid environment, triticale and barley have comparable yields with a small superiority for triticale in grain yield after forage use and higher plant and grain protein contents in barley.

Key words: Cereals defoliation, forage, protein, grain.

INTRODUCTION

In Tunisia, farmers face serious problems of low quantity and quality of forage to feed their animals. The year-round maintenance of pastures and production of forage crops is difficult to achieve in rain fed areas. This is caused by low and erratic rainfall and poor soil fertility conditions, which characterize the semi-arid and arid regions. One of the solutions, used mainly by local and small farmers, is the practice of dual-purpose cereals; these cereals are grazed or cut at a young stage (tillering) and then allowed to re-grow up to grain production. This will provide forage during winter season which is known as a forage deficit, reduce pressure on other feed resources and allow farmers to harvest grain and straw at the end of plant cycle. In Tunisia, dual-purpose use of cereals is commonly practised by Small ruminent breeders. The main crop serving as winter grazing and grain for feed is barley with 45000 ha annually which represents about 20% of total forage area.
(Ouji et al., 2010)

The most frequently used species for dual-purpose cropping in the Mediterranean context are barley, oats and triticale (Epplin et al., 2000). Biomass productivity before grazing and grain yield after regrowth define the suitability of these cereal species to dual-purpose practice. Researches about cereals dual-purpose for seeds and forage have given widely varying results according to the climate, to fertilization to the species, to seed rate and date and to the cut or grazing stage. In fact, the practice of first use by cutting or grazing helps to gain a certain amount of nutritious forage, but may reduce straw and grain production particularly when conducted in late growth stage. This practice is common in Morocco (Belaird and Morris, 1991); Syria (Mazid and Hallagian, 1983) and Tunisia (Amara et al., 1985). In Mediterranean environments, Hadjichristodoulou (1991) reported that grazing affected grain yield of dual-purpose barley in rain fed conditions, while the same effect was not detectable in irrigated conditions. According to the same author; one clipping at tillering stage reduced total dry matter yield by 12 to 64% and crude protein by 30%. Thus, the management of cutting stage influences the forage and grain yield. Royo et al. (1997) have reported that, when cut at the first detectable node stage (C. 31) triticale and barley forage yield was almost double the yield at the pseudo-stem erect stage (C. 30). Defoliation during early growth stages optimizes seed yield and forage quantity and quality (El-Shataweli et al., 2004). According to Giunta et al. (2015), understanding phenology is critical for the success of a dual-purpose crop as it determines both the duration of the grazing period and affects the recovery period. Decreases in grain yield after clipping have been attributed to a reduced number of spikes/m² at harvest in barley (Scott et al., 1988) and triticale (Royo et al., 1993) and also to a reduced grain number (Bonachela et al., 1995) and kernel weight (Royo et al., 1994).

Other studies have reported a grain yield increase after a cutting or grazing during green stage. This increase has been associated to the decrease of lodging (Droushiotis, 1984). Other results showed also that a properly managed grazing does not reduce grain yield in the dual-purpose system. It shows that the stocking pressure and number of cuts have been shown as important factors that influence the subsequent grain yield (Arzadun et al., 2003; Hossain et al., 2003). Epplin et al. (2000) and Hossain et al. (2003) also suggested that an optimal choice of planting date and density is crucial if cereal is to produce high forage and grain yields.

Other studies dealt with the influence of dual-purpose cereals on quality traits (Royo et al., 1994; Garcia del Moral et al., 1995; Royo and Pares, 1996; Royo et al., 1997; Royo and Tribó, 1997; Khalil et al., 2002b). With the exception of kernel weight, Khalil et al. (2002b) did not find detrimental effects of dual-purpose management on wheat grain protein or on dough strength parameters, nor was grain protein content affected by forage removal in barley and triticale (Royo et al., 1997). Royo et al. (1993) reported that triticale was seen to be good for forage production compared with other cereals, and barley had the highest crude protein content. The results also showed that different varieties of the species investigated had different behaviors with respect to their dual-purpose capacity. This result was contrary to that found by Khalil et al. (2002a) who found no significant differences among wheat cultivars due to the management system.

The objective of this study was to investigate the effect of defoliation on grain production and quality of two dual-purpose species, triticale and barley under rainfall conditions in a semi-arid region of Tunisia.

MATERIALS AND METHODS

The present study was carried out over 2 years (2010-2011 and 2011-2012) in el Kef region, in the experimental field of the higher Institute of Agriculture Kef (36° 11’ 9” N, Longitude 8° 42’ 59” E ; Altitude 652 m). The trial was carried out in a clay-sandy-loamy soil with about 25 cm ploughable soil and with low organic matter content (1.8%). The climate is Mediterranean, with rainfall concentrated in the autumn and winter. The average annual rainfall is 419 mm on the basis of 20 years.

Monthly rainfall as well as maximum and minimum temperatures of the two seasons of trial are reported in Figure 1. Rainfall from October to June was 496 mm in 2010/2011 and 508 mm in 2011/2012, which is above the annual average (419 mm). Both seasons had a wet winter (December, January and February) with 167 mm during first year and 244 mm for the second year. But greater rainfall was registered during March and April of the second year (143 mm) compared to same period of the first year (51 mm). It supposes that the regrowth of tested cereals will be better during 2011/2012 season.

The experiment assessed the response of two cereal species to winter clipping. Triticale (triticosecale Wittmack) variety Tcl 83 and barley (Hordeum vulgare L) variety Martin. In Northwest region of Tunisia, Triticale has been introduced as an alternative to barley by local farmers during last decade. The two chosen cultivars, Martin for barley and Tcl 83 for Triticale are very common in Tunisia. They are used for forage or for grain. Ben Youssef et al. (2001) and Ouji et al. (2010) have reported that Martin cultivar is good to be used in dual-purpose management.

The experimental design was a split plot with four replications and each plot measured 6 m² in which the main factor was the species and the secondary one the treatment. The two management systems (treatments) experimented were: (i) control plots which were only clipped at plant maturity in order to estimate the grain yield and (ii) dual purpose plots which were clipped first time and harvested as forage at the stem erect stage (C30) and then let regrowth up to plant maturity. For both treatments the whole plant was hand harvested at maturity and straw and grain yields (SY and GY) were estimated. Sowing was carried out early October (06 October 2010 and 08 October 2011 respectively for the first year and second year of the experiment) at a density of 300 viable seeds/m². The soil was chisel plowed in September and just prior to sowing. Pre-sowing fertilization rates for all plots were 46 kg P/ha and 18 kg N/ha. During growth cycle 2 fertilizations were provided: 40 Kg N/ha in 3 leafs stage and 50 Kg N/ha after clipping for dual-purpose treatments and in elongation stage for grain only use treatments. Weeds and diseases were chemically controlled.
Forage harvest was done on 13 February 2011 and 19 February 2012 for barley and 24 February 2011 and 26 February 2012 for triticale respectively for the first year and second year of the experiment. Plants were cut about 12 cm above ground level. Grain harvest was made at plant maturity on 28 June 2011 and 01 July 2012 for both species.

Fresh biomass production from each dual-purpose plot was determined at harvest and it's reported in tones of dry matter per hectare (TDM/ha). A 500 g sample was also taken for chemical analysis. The samples were dried to constant weight at 65°C in a forced-air oven. Milk feed units (MFU) were calculated after the energy production equations of Chase (1981). Forage and grain crude protein content were evaluated by means of the standards micro-kjeldahl procedure. Grain yield (GY), number of spikes/m² (NS/m²), number of grains per spike (NG/Sp) and thousand-kernel weight (TKW) were determined for each plot at seed maturity. Analyses of variance (ANOVA) were performed using (1985) and means were separated using Duncan Test.

RESULTS
Influence of defoliation at C30 stage and species on grain yield, straw production, yield components and forage production

Results of forage quantity harvested in C30 are shown in Table 1. Forage yield did not depend on the species. Barley and triticale has given comparable quantities of forage and only a slight superiority was noticed for barley compared to triticale, respectively 2.45 and 2.3 t/ha as average of the two years of trial. For both species, herbage dry matter was superior during the first year of the experiment (2010/2011) but without being statistically different.

The results of the analysis of variance for grain yield and its components are shown in Table 1. Cutting at the green stage (C30) has caused reduction of grain yield for dual-purpose use comparing to grain use only management system. This reduction was more pronounced for barley (-28 and -27% respectively for 2010/2011 and 2011/2012) than for triticale (-19 and -23% respectively for 2010/2011 and 2011/2012). For both species this reduction was statistically significant (P < 0.01). In the other hand, when they were not cut in C30 stage, barley and triticale had similar yields, which were not statistically different (3.92 t/ha for barley and 4.41 t/ha for triticale as average yields for the two years). For dual-purpose management system, triticale seems to be more adapted and has given a grain yield of 3.47 t/ha which is significantly higher (P < 0.05) than barley grain yield (2.85 t/ha). The interaction treatment x species was significant (P < 0.05) for grain yield.

The spike number/m² increased from 330 to 394 spikes/m² for barley and from 310 to 332 spikes/m² for triticale as average for the two years of experiment. This range of variation was statistically significant (P < 0.05). In the other hand, spike fertility was significantly affected only by treatment (P < 0.05). Number of grains/spike has decreased after clipping by 30% for barley and 20% for triticale. The third yield component, thousand-kernel weight, was a very stable variable, being similar for both treatments. It was not significantly affected by forage use neither by the species.

Straw quantity is also important for cereals producers in general and for animal keepers in particular, as it constitutes an alternative nutrition resource mainly during deficit period. With this trial, it appears that triticale gives more straw quantity in both managements systems (P < 0.01). Clipping has affected significantly straw production, and reduced it by (33%) for barley and (28%) for triticale (P < 0.05). For both cereals, this reduction was more pronounced during the second year of the experiment 2011/2012. The interaction between species...

and harvesting treatment was significant (*P <0.05). The higher straw quantity was obtained with triticale used for grain only.

Influence of defoliation at C30 stage and species grain and forage protein content

Results of this study indicated that forage barley has a higher protein content (182.6 g/kg DM) than forage triticale (174.2 g/kg DM) when it is cut at C30 stage. Analysis of variance has shown that this difference is significant (*P <0.05) (Table 2).

This experiment has also shown that in two years of trial, dual-purpose cultivation affected positively the grain protein content of the two tested species. Clipped plant in C30 stage has given grain more rich in protein: 113.56 g/kg DM Vs 101.76 g/kg DM for barley and 95.57 g/kg DM Vs 93.88 g/kg DM for triticale. This increase of grain protein content between treatments was significant only for barley (*P <0.05). The forage nutritional value, expressed as MFU/kg DM, was on average 0.78 MFU/kg DM for triticale and 0.68 MFU/kg DM for barley and showed statistical variation linked to the species (*P <0.05).

DISCUSSION

Winter cereals were grown for the dual-purpose of forage and grain as an alternative to grain production only in a semi arid climate. The objective was to produce forage during winter (a season of scarce forage supply in the area) and to evaluate effects of clipping on grain production, which have been usually observed (Hadjichristodoulou, 1991; Royo et al., 1997; El-Shatnawi et al., 2004; Droushiotis, 1984).

In our experiment, triticale and barley have given similar forage production, between 2.29 and 2.46 DM t/ha for both species and during the two experimental years. This could be attributed to the fact that the cutting stage (C30) is too early and that different species could not express differences in biomass production. Specific traits for each species will be more observable after cutting regrowth. Royo et al. (1997) have reported, under Mediterranean conditions, similar forage yields in first detectable node stage for triticale (2.03 t/ha) and barley (2.11 t/ha).

Yield components were differently affected by dual-purpose treatment. Thus, Clipping at C30 stage has enhanced spike number production barley and triticale. This is explained by the removal of the apical domination during final stage of the tillering period. In fact, with defoliation the predominant apex is eliminated and then tiller production restarts again and could drive to a higher number of productive tillers per plant (Briske and Richards, 1994). Bonachela et al. (1995) have also found that forage use during winter makes the tillering period

Conclusion

Of the two crops studied, triticale demonstrates clear superiority in the grain yield, milk feed units value and straw production over barley in the dual-purpose system conditions during February and March have allowed a good restart of tillering and then more spikes per plant, which was associated with a reduction of grain number per spike.

In our study, protein produced in forage was superior in Barley compared to Triticale and averaged 182.3 g/kg DM for barley and 174.9 g/kg DM for triticale and This is in accordance with Royo et al. (1997) results who have measured around 172 g/kg DM for triticale cut in C30 and C31 stages and around 189 g/kg DM for barley cut at same stages. In the contrary, triticale forage has shown better energy content than triticale 0.78 MFU/kg DM vs 0.68 MFU/kg DM. In the other hand, grain protein content was positively affected by defoliation for both species. The significant increase of grain protein after defoliation in C30 stage could be attributed to the dilution effect, since the grain yield was decreasing after clipping and the number of spikes per plant was higher. The higher content of grain protein for dual-purpose use could also be explained by a higher consumption of nutrients than in only grain use. This conclusion joins results of Francia et al. (2006) who have reported also an increase of grain protein content after clipping during green stage for barley and oat.
in the semi-arid region of Tunisia. Triticale has shown good regrowth after clipping in green stage and reduction of grain yield did not exceed 22%, although barley grain yield was reduced by 29% after forage removal during tillering stage. In the other hand, barley has given grain and forage more rich in protein than triticale and this for both management systems.

Triticale has specific morpho-physiological traits that make it more suitable to dual-purpose cultivation than other cereals. It is highly efficient in the utilization of water and nutrients in limiting conditions, a good capacity for tillering, and high capacity for regrowth after forage use; that, in addition to its capacity to compete, enables a fast and large accumulation of biomass. Further research which study the economic impact of dual purpose management of Triticale compared to only grain use may aid to make the choice for the dual or single use of triticale and barley.
