UNIOESTE – Western Paraná State University – Post-graduation Program, Master Course of Energy in Agriculture, Rua Universitária, 2069, CEP: 85.819-130 Bairro Faculdade, Cascavel, Paraná, Brasil.

Received 5 June, 2013; Accepted 16 April, 2014

The aim of this study was to evaluate the effect of the weed competition with different spacings in the culture of flaxseed (*Linum usitatissimum* L.). The experiment was conducted at the Campus of Unioeste - Cascavel, Paraná State, using the split-plot design in which the plots consisted of presence and absence of weeds and subplots consisted of row spacings (0.15, 0.30, and 0.45 m) with six replications. Plant height, number of capsules, stems and seeds per plant and yield (kg.ha⁻¹) were determined. The increase of spacings between rows and the coexistence with the weed community were detrimental to production components of flaxseed.

Key words: *Linum usitatissimum* L., competition, spatial arrangement of plants.

INTRODUCTION

Flaxseed (*Linum usitatissimum* L.) is a herbaceous plant that belongs to the Linaceae family, with more than 200 recognized species (Cui, 1998). The energy use of flax seeds can give a new direction to this culture, since its seed is rich in oil. The seeds contain about 38% oil, that once extracted can be used to produce biofuels (Rabetafika et al., 2011).

Spacing and spatial arrangement are the main factors related to the degree of interference between crops and weeds, as they act on the precocity and intensity of shading of the crop over weeds (Dias et al., 2009; Tharp and Kells, 2001; Norris et al., 2001; Knezevic et al., 2003). Balbinot and Fleck (2005) emphasize that the competitiveness of crops is dependent on factors such as: cultivated species, morphological and physiological characteristics of the genotypes, weed species present in the area and time of their emergence, and also environmental conditions, especially temperature, solar radiation and rainfall.

Barreyro and Valduvi (2002) determined the critical period of interference for the culture of flaxseed between 30 and 80 days of sowing, observing significant losses when the culture was subjected to infestation throughout the cycle. The authors emphasize that it is a tool to reduce damage by weeds and use different alternatives for management and control. Several studies have been developed to analyze the behavior of the infestation in the spatial distribution of crops between rows of soybean (Melo et al., 2001), beans (Burnside et al., 1998) and corn (Ramos and Pitelli, 1994) and peanut (Pitelli et al.)
2002). However, studies on flax are practically nonexistent.

One way to increase the competitiveness of the crop is by reducing the spacing, so that the crop canopy closes between rows faster and shades the weeds. In that sense, the purpose of this experiment is to investigate the potential development of golden flaxseed (*Linum usitatissimum* L.), with and without weed infestation in different row spacings.

**MATERIALS AND METHODS**

The experiment was conducted under field conditions in the agricultural year of 2012, during the period from April to August 2012 at UNIOESTE (State University of Western Paraná), located in the city of Cascavel, Paraná, Brazil, latitude 24°53'47" S and longitude 53°32'09"W. The region presents mesothermal and super humid temperate climate, Cfa climate type (Koeppen) (Caviglione et al., 2000). The average annual temperature in the region is 19.6°C, annual rainfall of 1971 mm and 2462 h of sunshine per year (IAPAR, 2011). Monthly averages of temperature and precipitation are shown in Figure 1 and Table 1.

The experimental setup used was the split plot scheme, in which the plots consisted of the presence and absence of weeds and subplots consisted of row spacings (0.15, 0.30, and 0.45 m) with six replications. The subplots consisted of six rows (5 m long), with a useful area of four central lines. The sowing of flaxseed was held manually on April 14th, 2012 in the lines starting with a manual furrowing. As for the sowing operation, a final population of 333,000 plants ha⁻¹ was obtained to all spacings. Base fertilization rate was 200 Kg ha⁻¹ of formula 02-20-18. Weed control in the area with no competition was carried out manually. No agrochemical was applied during the experiment. The following characteristics were evaluated: plant height, number of stems, seeds and capsules per plant and yield (Kg ha⁻¹). In order to determine the parameters of production ten plants in each plot were sampled. Grain yield was obtained by manual harvesting of central lines in each experimental unit. Subsequently, the tracking and weighing of grains took place. The yield was corrected to 13% moisture, and results were expressed in Kg ha⁻¹.

In order to characterize the weed community in treatments where the crop was under interference, two frames of 0.25 m² were sampled. Weeds were collected, identified and counted. The results were submitted to analysis of variance and the interaction between factors and their means were compared by Tukey's test at 1 and 5% probability, using the statistical package Assistat® version 7.5 beta (Silva and Azevedo, 2002). Data unfolding was performed when the interaction infestation x spacing was significant.

**RESULTS AND DISCUSSION**

The weed community consisted of the following species: *Raphanus sativus* (8.19%), *Lolium multiflorum* (16.78%), *Sonchus asper* (1.12%), *Galinsoga parviflora* (0.29%), *Bidens pilosa* (0.14%), *Ambrosia elatior* (5.05%), *Mollugo verticillata* (24.53%), *Taraxacum officinale* (23.20%), *Facelis apiculata* (3.68%), *Croton glandulosus* (2.35%), *Eupatorium pauciflorum* (3.04%), *Fumaria officinalis* (2.74%), *Diodia teres* (0.98%), *Richardia brasiliensis* (4.90%), *Bromus catharticus* (2.06%), *Emilia fosbergii* (0.44%), *Sida rhombifolia* (0.44%).

The rainfall at the experimental site (Figure 1) was considered good for the development of the culture, despite the uneven distribution, it can be said that the production performance was not influenced by soil water deficit. According to Hocking et al. (1997) and House et al. (1999), factors such as low rainfall and high temperatures during the anthesis and grain filling stage have a significant effect on flaxseed yield.

The performance of the analysis of variance is presented in Table 2. One can observe a significant difference for all production components analyzed in relation to infestation. The spacings did not influence in plant height. The interaction between infestation x spacing did not affect the number of capsules per plant.

Plant height was influenced by infestation (Table 2) and by the interaction Infestation x Spacing. Regarding the level of infestation, it can be seen that when flaxseed was grown in larger spacings (0.45 m) interaction between the weed and the culture had no effect on plant height (Table 2). Melo et al. (2001), when determining the period previous to the interference in a soybean crop with row spacings of 30 and 60 cm found no influence of the presence of weeds in plant height as well as in the first pod insertion and 100 seed weight. Babington and Fleck (2005) found no significant effect of row spacing on plant height on a corn crop.

As for the number of capsules, one may note the significance of the infestation and spacing in relation to the component (Table 3). Interaction between factors did not influence the number of capsules per plant. The coexistence of culture with the infestation resulted in a reduction of 56% capsules per plant. Andrade et al. (1999) observed a reduction in the number of pods/plant in beans with greater spacing with coexistence due to the competition with weeds. According to the authors with greater spacing there is proper closing of the culture, providing greater infestation and better conditions for their development. According to Teasdale (1995), the adoption of smaller spacings increases the competitiveness of the crop with weeds due to the greater amount of light that is intercepted by the crop.

canopy. The number of stems, seeds and yield were affected by the infestation and spacing, as well as the interaction between Infestation x Spacing. Due to the interaction between factors, the unfolding was analyzed in Table 4.

One can verify in what concerns to the number of rods that when the culture was subjected to living with weeds spaced 0.45 m between rows there was a reduction from 3.16 to 1.66 stems per plant. Note that when the culture was kept free from weeds the spacing of 0.45 m between rows provided a greater number of stems per plant.

When observing the differences in the unfolding of interaction infestation x spacing (Table 4) for the component number of seeds per plant, one can notice a negative influence of the coexistence of the crop with the infestation, resulting in the decrease of seeds per plant, matching what was stated by Barreyro and Vallduvi (2002); Vallduvi et al. (1997) and Gruenhagen and Nalewaja (1969). When the crop was under infestation there was no difference between the spacings in the production component, however with the spacing of 0.15 m between rows, the infestation did not harm the crop. The highest number of seeds per plant was observed with the spacing of 0.30 m, with no infestation.

For two corn genotypes with presence of weeds, Balbinot and Fleck (2005) observed reduced stem diameter, plant height and all components of grain yield with 11% reduction in the number of grains per ear due to infestation. The yield was influenced by the interaction between infestation x spacing (Table 4). The competition did not affect the productivity with spacing of 0.45 m between rows, but there was an increase of 32 and 70% in the spacings of 0.15 and 0.30 m, respectively, in relation to infestation. Row spacing did not affect productivity when culture competed with weeds. Balbinot and Fleck (2005) obtained better results in grain yield of maize with reduced spacing and no competition.

Barreyro and Vallduvi (2002) found loss of 63, 54 and 79% in 1993, 1994 and 1995 respectively, in the yield of flaxseed when submitted to the competition throughout the cycle. Dias et al. (2009) observed a reduction in productivity from 2,054 to 341 Kg.ha⁻¹ in a peanut crop with spacings of 0.8 m between rows due to the interference of weeds, what represents 83% loss of productivity. For the distance of 0.9 m, the coexistence of 140 days between weeds and crop resulted in a production decrease from 1,820 to 82 Kg.ha⁻¹, which is equivalent to 95%.

Conclusion

There is an influence of the interaction of factors infestation and spacings on flaxseed development. The lowest row spacing did not affect crop productivity when it was subjected to infestation.
