The use of different legume species, as green manure, may affect differently soil biological and chemical properties. The aim of this study was to evaluate the effect of four legumes species used as green manure on soil biological and chemical properties in short-term. We evaluated the following legume species: Crotalaria, Cajanus, Mucuna and Canavalia. The study was arranged in a completely randomised design with four replicates. The plants were incorporated into the soil (0-20 cm) by harrow and the chemical and biological properties were evaluated 30 and 60 days from the incorporation. Soil chemical and biological properties showed different trends according to legume species used. Soil P and K contents were highest in plot with Crotalaria, while soil Ca content was highest in plot with Mucuna. Soil microbial biomass was higher in plot with Mucuna as compared with others green manure species. Fluorescein diacetate hydrolysis was higher in plots with Mucuna and Canavalia than the others plots. Our results supported the hypothesis that different types of legume used as green manure affect differently the biological and chemical properties of soil. In this case, Mucuna was more effective to improve soil biological properties, while Crotalaria seems to be more efficient in the improvement of chemical properties.

Key words: Organic fertilization, alternative agriculture, legumes.

INTRODUCTION

The use of legumes species as green manure is an important practice for sustainable agriculture as the legumes may fix N and have deep and extensive root system, allowing greater extraction and recycling of plant nutrients. Some studies have shown the great potential of green manure for supplying nutrients to crops (Perin et al., 2004; Adediran et al., 2004) and the improvement of soil properties (Adediran et al., 2004; Ziblim et al., 2013). However, several legume species may be used as green manure and each one presents different properties which may affect differently the soil properties. Also, the influence of organic residues on soil properties depends upon the amount, type and size of the added organic materials (Zhang et al., 2015). Among the legume species used for green manure in tropical regions, the Canavalia is one of the most favorable for agricultural use.
by their morphological and physiological characteristics (Heinrichs et al., 2002), while *Crotalaria* is very efficient as producer of plant dry mass (Ziblim et al., 2013). *Mucuna* is other legume species which has a potential for soil restoration, improving the chemical and physical properties of the soil (Alvarenga et al., 1995). Finally, *Cajanus* presents deep root system with high potential in water absorption and recycling of nutrients from deep layers (Alvarenga et al., 1995).

Although it is widely known that green manure and others crop residues improve the soil chemical and biological properties (Biederbeck et al., 2005; Liu et al., 2006; Shah et al., 2010; Ye et al., 2014; Adediran et al., 2004; Ziblim et al., 2013), there is the need to compare the different legume species in the improvement of soil biological and chemical properties in the short-term as usually these soil properties may respond quickly to soil management according to chemical characteristics of organic residue.

As an important biological property, soil microbial biomass is used as an ecological attribute to evaluate changes in soil properties by soil use and management (Lopes et al., 2010; Santos et al., 2012). In addition, soil microbial biomass releases enzymes which play important functions in soil processes, such as the decomposition of organic matter (Silva et al., 2012). Thus, soil enzyme activity may be used as an indicator of soil quality due to its control on microbial growth (Burns et al., 2013). For chemical properties, Smith and Doran (1996) suggested that soil total organic carbon (TOC), available P, exchangeable K and soil pH are important measurements of soil quality because they provide indicators of soil nutrient supplying capacity.

We hypothesized that each legume species presents different chemical composition and therefore affect differently soil biological and chemical properties in short-term. Thus, the aim of this study was to evaluate the effect of four legumes species used as green manure on soil biological and chemical properties in short-term.

### MATERIALS AND METHODS

The experiment was located at the Experimental Area from Agricultural Science Centre, Teresina, Piauí, Brazil. The regional climate is dry tropical (Köppen) and is characterised by two distinct seasons: Rainy summer and dry winter, with annual average temperatures of 30°C and rainfall of 1200 mm. The rainy season extends from January to April, when 90% of the total annual rainfall occurs. The soil is classified as a Fluvisol with the following composition at 0 to 20 cm depth: 10% clay, 28% silt, and 62% sand.

The following legume species were evaluated: *Crotalaria*, *Cajanus*, *Mucuna* and *Canavalia*. We included a treatment without green manure as a reference (control). The experimental area was arranged in a completely randomised design with four replicates. Plots measured 10 m² each, with 6 m² of usable area for soil sampling and rows spaced 0.4 m apart. *Crotalaria* and *Cajanus* were grown at a density of 10 plant m⁻¹, while *Mucuna* and *Canavalia* were grown at a density of 7 plant m⁻¹. After 60 days from the sowing (flowering), all plants inside the plots were harvested and incorporated into the soil (0-20 cm) by harrow.

Chemical characteristics of the legume species are shown in Table 1 (Cavalcanti et al., 2012). After 30 and 60 days from the incorporation, five soil samples were collected (0-20 cm) in each plot (from usable area) using a spade and pooled to form a composite sample per plot. Each soil sample was sieved (< 2 mm) and stored prior to analysis. Soil pH was estimated in water (1:2.5 v:v) and measured using a pH meter (Tedesco et al., 1995). Available P and exchangeable K, Ca, and Mg were evaluated according to chemical characteristics of organic residue.

### RESULTS

The incorporation of green manure changed the soil
Table 2. Chemical properties of soil after 60 days of incorporation of green manures.

*Control, plot without green manure.

The incorporation of green manure, in short-term, did not promote different in soil organic C content at 30 and 60 days after green manure application. Soil biological properties changed with the incorporation of green manure (Table 3). The incorporation of green manure promoted an increase in MBC as compared with soil without green manure. However, soil MBC showed different behavior according to the green manure incorporated. Thus, plots with Mucuna showed highest values of MBC at 30 and 60 days as compared with others green manure species. There was an increase in soil MBC from the 30th to 60th days of evaluation for all plots with green manure. At 30th day, the microbial quotient (qmic) was higher in plot with Mucuna; while at the 60th day there was not difference between plots.

Soil microbial activity, as measured by basal respiration and FDA hydrolysis, increased with the use of green manure as compared with the plot without green manure (Table 3). However, the soil basal respiration did not differ between plots with green manure. On the other hands, FDA hydrolysis was higher in plots with Mucuna and Canavalia than the others plots. There were not differences in values of FDA hydrolysis between the 30th and 60th days of evaluation for all evaluated plots.

NMS analysis explained 81% of variation and clustered two main groups according to biological and chemical properties (Figure 1). The first group consisted of plot with Mucuna and was linked with soil microbial biomass C and FDA hydrolysis; while the other group consisted of plots with Guandu, Crotalaria and Canavalia and was grouped with soil basal respiration and microbial quotient.

DISCUSSION

The incorporation of green manure, in short-term, increased the content of some chemical elements in the soil, suggesting that this practice may improve the soil fertility shortly. Previous studies had shown the positive effect of green manure on soil fertility in short-term (Astier et al., 2006; Partey et al., 2014). The legume species promoted different responses of soil chemical properties and it occurred due to different composition of each green manure. The higher values reported for soil P and K content in plot with Crotalaria are due to decomposition of the green manure, which presents high content of P and K in its composition (Table 1) and contributes for the releasing of these elements to the soil. Similar results
were found by Ziblim et al. (2013) comparing the potentials of Mucuna and Crotalaria as green manure on soil fertility, where they observed that Crotalaria added a higher amount of available P and K as compared to Mucuna. It is important for the improvement of soil fertility and may provide essential nutrient for crops. On the other hands, Mucuna presented high Ca content in its composition and it contributes for the increase in soil Ca in soil with this legume specie. These findings are in agreement with Adediran et al. (2004) which evaluated the effect of Mucuna intercropped with maize (Zea mays L.) on soil fertility and observed, after two months of Mucuna application, the increasing in the content of exchangeable Ca by 81% when compared with the chemically fertilized soil.

Our results showed that soil organic C did not change, in short-term, with the addition of green manure indicating that soil organic matter is not sensitive to short-term changes of soil quality with different soil or crop management practices (Liu et al., 2013). Usually, soil organic C increases in medium- to long-term as reported in previous studies (Dou et al., 2006; Huang et al., 2010).

On contrary, soil microbial biomass is a sensitive indicator of soil quality and responds quickly to changes in soil management. Several studies reported that soil microbial biomass improved significantly by using of legumes as green manure (Biederbeck et al., 2005; Liu et al., 2006; Shah et al., 2010). The results showed that soil microbial biomass and showed different values according to legume specie as also reported by Shah et al. (2010) who evaluated six types of legumes as green manure and observed that soil microbial biomass varied with the type of legume, where the highest microbial biomass was found in soil with sesbania and lowest in plot with guar. In our study, the higher soil MBC found in plots with Mucuna occurred due to its high input of dry mass with low C/N ratio which increases the availability of C to soil microorganisms (Franchini et al., 2007). It may suggest that this legume specie presents high potential to improve soil biological properties as reported by Blanchart et al. (2006) who evaluated the use of Mucuna as cover crop and found a positive modification in diversity and composition of soil biota.

On the other hands, the increase in soil microbial biomass from 30th to 60th day suggests that the all green manure maintained C source to soil microbial biomass. It may have occurred since the legumes are applied on soil surface and releases slowly the C for soil microbial consumption. Therefore, there is an increasing in soil microbial biomass over-time. The highest microbial quotient observed in plot with Mucuna is due the higher soil microbial biomass found in this plot. As the microbial quotient
quotient is an indicator of availability of organic C for soil microorganism (Anderson and Domsch, 1989), this result means that in plot with Mucuna the organic C is more available for soil microbial biomass (Steiner et al., 2008).

Soil management practices which modify the soil microbial biomass also affect the enzyme activities (Dick et al., 1996). The FDA hydrolysis is directly proportional to the microbial growth (Swisher and Carroll, 1980) and is involved in the transformation of soil organic matter (Sicardi et al., 2004). Also, FDA hydrolysis is a good indicator of soil microbial activity and reflects the activity of several enzymes, including lipases, esterases and proteases, and its activity increases with SMB (Schnurer and Rosswall, 1982). Our results showed that microbial metabolism was positively influenced by Mucuna and Canavalia, suggesting these legume species may increase the soil microbial activity.

The NMS analyses of the soil biological and chemical properties revealed distinct trends for the legume species used as green manure. The plot with Mucuna clustered, at 30th and 60th days, and was characterized by higher microbial biomass C and microbial activity. This may suggest that this legume species has a potential to improve soil biological properties. On the other hand, Crotalaria, Guandu and Canavalia clustered together and were characterized by basal respiration and microbial quotient, which can be indicative of higher decomposition and availability of C and others nutrients.

Conclusion

Our results supported the hypothesis that different types of legume used as green manure affect differently the biological and chemical properties of soil. It occurs mainly due the different chemical composition of each legume species used. In this case, Mucuna was more effective to improve soil biological properties, while Crotalaria seems to be more efficient in the improvement of chemical properties.
