Sweet grain sorghum [Sorghum bicolor (L.) Moench] is an under-harvested crop produced mainly for its sweet grains in the pasty stage. Little is known of its genetic diversity remains. This study aims to determine the level and structure of the genetic diversity of sweet grain sorghum from Burkina Faso. Thus, 93 accessions were evaluated using 15 polymorphic microsatellite markers. The analysis revealed 49 alleles in total, 6 rare alleles, an average of 3 alleles per locus, a moderate Nei diversity of 0.474, a low level of heterozygosity (0.031) in the collection and very high Wright's fixation index (Fis) of 0.934. The accessions were organized into three genetic groups: A, B and C. Groups A and B were the farthest, with an Fst and a genetic distance of 0.37 and 0.22, respectively, whereas Groups B and C were the closest, with an Fst (genetic differentiation) of 0.279 and a genetic distance of 0.142. This diversity could be exploited in Burkina Faso sweet grain sorghum breeding programs.

Key words: Burkina Faso, neglected culture, sorghum, simple sequence repeats (SSR) markers, genetic variability.

INTRODUCTION

Traditional varieties are an important source of genetic diversity whose conservation contributes to the maintenance of genetic diversity (Ahmadi et al., 1988). Knowledge of the level and structure of their genetic diversity is an important asset in defining strategies for conservation and varietal improvement (Adoukonou-Sagbadja et al., 2007).

Previous studies on sweet grain sorghum with phenotypic markers have shown an important agromorphological variability in the collection from Burkina Faso (Sawadogo et al., 2014). However, the observation of morphological characters can lead to a biased estimation of genetic diversity because they are influenced by the environment. Indeed, phenotypic diversity may be increased but genetic diversity remains stable (Lallemand, 2004). For a better estimate of the...

</table>

genetic diversity of sweet grain sorghum from Burkina Faso, it is imperative to evaluate it using molecular markers.

The development of genome mapping techniques and their associated attempts to link molecular variability with phenotypic variability are likely to become increasingly acute (Pham et al., 1992). Nuclear molecular markers, in particular microsatellites, otherwise called simple sequence repeats (SSR) are very polymorphic (Doldi et al., 1992). They are codominant and abundant in the genome, easy to use and highly effective in the studying of genetic diversity (Lagercrantz et al., 1993).

The present study was conducted to get a better knowledge of the genetic diversity of the Burkina Faso sweet grain sorghum. The objectives are to: (i) determine the level and (ii) structure of the molecular genetic diversity of sweet grain sorghum from Burkina Faso.

MATERIALS AND METHODS

Plant and molecular markers

The plant materials consisted of 93 accessions of sweet grain sorghum from Burkina Faso obtained by self-fertilization in 2010. Fifteen simple sequence repeat (SSR) markers were selected based on their polymorphism revealed in previous studies on sorghum (Barro-Kondombo, 2010; Nebié, 2014), and their distribution on all the chromosomes of the sorghum genome (Table 1) were used for characterization.

Extraction of total DNA

The total genomic DNA of the 93 accessions was extracted from young freshly picked leaves of 15 days. Flinders Technology Associates (FTA) card method was used for the extraction of DNA. The method works faster from DNA extraction to DNA amplification by polymerase chain reaction (PCR). It consists of taking the fresh young leaves and crushing them on the rough side (square) of the FTA card. The samples were dried in 30 min; then disks of 1 mm diameter were punched, which were placed in Eppendorf tubes. 200 µl of FTA buffer was then added to the punched disks. The whole was incubated at a room temperature for 5 min. This operation was repeated three times by renewing the buffer. At the end, the disks were rinsed with 200 µl of TE (Tris-EDTA) buffer (10 mM Tris·HCl, 0.1 mM EDTA, pH 8.0) and then dried for 5 min before transferring directly each disk in an Eppendorf tube for polymerase chain reaction (PCR).

PCR amplification of genomic DNA

DNA amplification was performed with the thermocycler Eppendorf Master Cycler Gradient in a total volume of 25 µl containing 18 µl of ultrapure water for each sample, 5 µl of premix (with 1 U of Taq (Thermus aquaticus) DNA polymerase, 250 mM of dNTPs, 10 mM Tris·HCl, 30 mM KCl, 1.5 mM MgCl₂, 1 µl of each primer microsatellite F (Forward) and R (Reverse) and one disk of FTA card (0.25 to 0.5 ng/µl genomic DNA) for each sample. A marker of molecular weight of reference of 50 bp (base pairs) and a control without DNA were used. The PCR amplifications were performed in an Eppendorf Master cycler: it comprises an initial denaturation phase at 94°C for 4 min followed by 35 cycles of denaturation step at 94°C for 45 s, annealing at 50 to 55°C for 1 min and an extension at 72°C for 1 min 30 s and final extension at same temperature for 4 min.

The PCR products were separated for 1 h 30 min at 100 V on 2% agarose gel in TBE (Tris-Borate Ethidium) 0.5x and 15 µl of BET 5% (ethidium bromide), using fluorescent developer. The revelation of the amplification products was visualized on an UV transilluminator and photographed with a camera brand Canon Power Shot A620, 7.1 Mega Pixels. The size of DNA bands in base pairs was determined using the 1 kb DNA standard ladder (Invitrogen, Carlsbad, CA, USA).

Statistical analysis

Genetix 4.03 (Belkhir et al., 2002) was used to determine the
observed heterozygosity (Ho). The total number of alleles (A), mean number of alleles per locus (A), number of rare alleles (A'), the polymorphic information content (PIC) and the expected heterozygosity (He) were known using Fstat software V2.9.3.2 (Goudet, 2002).

The dissimilarity coefficients were used to generate an unweighted neighbor-joining tree with Jaccard’s similarity coefficient and a bootstrapping value of 1,000 using the DARwin V5.0 software (Perrier et al., 2006). Wright’s fixation index (Fis), genetic differentiation between genetic groups based on Fst (Weir and Cockerham, 1984) and minimum distance of Nei between pairs of genetic groups were estimated using Fstat software V2.9.3.2. To verify the significance of the differences in these values, permutation (1000 to 3000 permutations) was carried out. From the Fis value, the allofecdration rate (t) was estimated using the formula Fis = (1-t) / (1 + t).

RESULTS

Genetic diversity of sweet grain sorghum

Results (Table 2) revealed that the number of alleles per locus varied from 2 for markers sbagb02, xtxp136 and xtxp295 to 5 for gpsb123, xtxp145, xtxp320 markers (Figure 1). Sbagb02 and xtxp145 markers have the extreme value of expected heterozygosity. The results indicate that only the locus: gpsb123, xtxp320 and xcup14 have observed heterozygosity values with an average of 0.03. The markers sb6-84 and xtxp145 showed extreme PIC values of 0.046 and 0.661, respectively.

A total of 49 alleles were detected in the collection with a low number of rare alleles (6), an average of 3 alleles per locus, and relatively low observed (0.031) and expected (0.474) heterozygosity. Results also show a very high value of Wright's fixation index (0.934) and a very low allofecdration rate (t) of 06.04%.

Organization of genetic diversity and description of genetic groups

Sweet grain sorghum from Burkina Faso is divided into three genetic groups: A, B and C (Figure 2) consisting of 40, 43 and 09 accessions, respectively. The characteristics of the three genetic groups are shown in Table 3. Group A has the highest number of alleles (43) including 6 private alleles, highest expected heterozygosity (0.42), and lowest observed heterozygosity (0.0107). Group B has the highest value of rare alleles (18), observed heterozygosity (0.051), and lowest expected heterozygosity (0.30). Group C has low number of alleles (34) and mean values for other genetic diversity parameters.

Genetic distance between genetic groups

The genetic distances between the three genetic groups revealed by the minimum distance of Nei and the genetic differentiation by pair of genetic groups (Table 4) show that the three genetic groups differed very significantly from one another. Groups A and B are the most remote while groups B and C are the closest.

DISCUSSION

The markers xtxp145 and xtxp320 that showed 5 alleles were the most polymorphic. But, they revealed more

The upper diagonal is the comparison of Fst by pair of genetic group and the lower diagonal (bold) is the minimum distance of Nei. **Significant at 1%.

The PIC of SSR marker that takes into account the number of alleles detected and the relative frequencies of these alleles constitute an important estimate of the discriminating capacity of this marker (Smith et al., 2000). The relatively high value of the PIC of the SSR markers used shows that they have had a undifferentiated. These results indicate that the diversity observed was lower than those of several previous studies (Nebié, 2014; Missihoun et al., 2015; Al-Issawi, 2017). The SSR polymorphism, the level of diversity of accessions in the collection, and the sensitivity of DNA fragment separation systems could explain these strong discriminating capacity for these genetic studies. The markers xtxp145, xtxp320 and gpsb123 were therefore

alleles in the sweet stalk sorghum of Burkina Faso, such as 12 for xtxp145 locus and 10 alleles for xtxp320 locus (Nebié, 2014). The PIC of SSR marker that takes into account the number of alleles detected and the relative frequencies of these alleles constitute an important estimate of the discriminating capacity of this marker (Smith et al., 2000). The relatively high value of the PIC of the SSR markers used shows that they have had a undifferentiated. These results indicate that the diversity observed was lower than those of several previous studies (Nebié, 2014; Missihoun et al., 2015; Al-Issawi, 2017). The SSR polymorphism, the level of diversity of accessions in the collection, and the sensitivity of DNA fragment separation systems could explain these strong discriminating capacity for these genetic studies. The markers xtxp145, xtxp320 and gpsb123 were therefore
the most discriminating with PIC greater than 0.6. But the maximum value of PIC per marker was lower than the value obtained by Amelework et al. (2015) and Galyuon et al. (2016): 0.88 and 0.89, respectively.

The 49 alleles detected show that the collection of sweet grain sorghum from Burkina Faso is relatively different. In addition, the very low proportion of rare alleles (12%) in the collection may be related to the small sample size and the much smaller geographic origin of accessions or to a low microsatellite marker mutation rate. However, rare alleles may be of great interest if they are related only to a few particular genotypes. They can be used to identify particular genotypes or specific genome regions related to a particular type of sorghum (Agrahama and Tuinstra, 2003). Indeed, Casa et al. (2005) and Salih (2011) detected 64 and 59% of rare alleles in more extensive collections.

The collection is relatively poor in heterozygotes due to the mean observed heterozygosity rate and the very high Wright’s fixation index (Fis). The Fis index was higher than the value of Barnaud et al. (2007), but similar value was obtained by Ouédraogo et al. (2017), which was 0.68 and 0.97, respectively. The observed heterozygosity rate was lower than the value of Salih (2011) but higher than the results obtained by Nebié (2014) (0.016) and Ouédraogo et al. (2017) (0.012). These results are probably related to the preferentially autogamous reproduction regime of species, the racial difference and the fact that accessions were obtained by self-pollination. The collection contains a large proportion of accessions close to the guinea whose glumes are open, which favors the allogamy whose rate can reach 24%, according to Barro-Kondombo (2010).

SSR markers are commonly used as a tool to examine the dynamics of differentiation in the population (Matsuoka et al., 2002) and for specific analyses (Liu et al., 2003; Barkley et al., 2006; Kwak and Gepts, 2009). The three genetic groups identified reveal a lower genetic diversity of sweet sorghum compared to sorghum in center and west of Burkina where Barro-Kondombo (2010) obtained 6 genetic groups. This low genetic diversity may be related to the more restricted range of these sorghum crops. The result is similar to those of Missihoun et al. (2015) who have obtained three groups with 61 accessions and 20 SSRs, while Muui et al. (2016) have obtained four groups with 20 SSRs and 44 accessions.

The study showed a weak genetic polymorphism in Burkina Faso sweet grain sorghum and a distribution of accessions into three genetic groups. The gpbs123, xxtp145, and xxtp320 markers were the most informative on the diversity of sweet grain sorghum and most discriminating. These results show that the molecular markers used were appropriate for the assessment of the genetic diversity of Burkina Faso sweet grain sorghum. A study of the phylogeny of these sorghums could allow to position them in relation to other sorghum and to complete the results of this study.
