Accepted 16 November, 2010

Studies were carried out to ascertain some kinetic properties of alkaline phosphatase (ALP) extracted from *Lepus townsendii* liver. Incubation of ALP extract with 4-nitrophenylphosphate (4-NPP) formed the basis for determination of enzyme activity. Spectrophotometric method was used to assay the enzyme activity, and the kinetic constants—maximum enzyme velocity (\(V_{\text{max}}\)) and Michealis-Menten constant (\(K_m\)) were evaluated. The \(K_m\) and \(V_{\text{max}}\) values were 0.5 \(\times\) 10\(^{-3}\) M and 20 \(\times\) 10\(^{-6}\) M/min, respectively. Inhibition studies showed that ALP activity was competitively inhibited by 0.67 mM sodium hydrogen orthophosphate (NaH\(_2\)PO\(_4\)) and the inhibition constant (\(K_i\)) was 0.9 \(\times\) 10\(^{-3}\) M. The optimum pH value for ALP activity was about 9.2, and optimum temperature registered was 45°C. ALP activity exhibited linear Arrhenius relationship at temperature greater than 44.95°C with corresponding catalytic energy of activation (\(E_a\)) = 15.23 KJ mole\(^{-1}\). The present study gave insights into characteristic catalytic properties of ALP extracted from *L. townsendii* liver.

Key words: Alkaline phosphatase, *Lepus townsendii*, 4-nitrophenylphosphate (4-NPP), Arrhenius relationship, Michealis-Menten constant.

INTRODUCTION

Orthophosphoric monoester phosphohydrolase (E.C.: 3.1.3.1), also referred to as “alkaline phosphatase” (ALP) is a generic term that describes a group of catalytic proteins sharing the capacity to hydrolyze phosphate esters in alkaline medium (Zhang et al., 2004; Saini et al., 2005). The enzyme contains a zinc atom (Zn\(^{2+}\)) near the active site that is viewed to be responsible for its catalytic activity (Le Du et al., 2001; Dean, 2002). Also, activation of ALP activity is facilitated by divalent cations such as magnesium (Mg\(^{2+}\)) (Kim and Wyckoff, 1990; Le Du et al., 2001; Dean, 2002) and cobalt (Co\(^{2+}\)) (Arise et al., 2008). Conversely, ALPs are inactivated/inhibited by wide range of compounds, depending on the source of the enzyme (Hummer and Millán, 1991; Hoylaerts et al., 1992). For instance, bone and kidney ALPs are inhibited by urea, whereas those obtained from placenta and gastrointestinal are unaffected but inhibited by phenylalanine (Dean, 2002). Also, ALP extracted from *Escherichia coli* is not inhibited by phenylalanine (Hoylaerts et al., 1992). The wide distribution of ALP in biologic systems coupled with its broad specificity makes the enzyme a readily available parameter for diagnostic and research studies (Garba and Gregory, 2005).

Reports showed that ALP extracts from different tissue/organ and various biological systems exhibit variable but characteristic kinetic properties that serve as basis for distinguishing ALP isoforms (Mayer-Sabellek, 1988; Dean, 2002). Therefore, the aim of the present study is to ascertain some kinetic parameters of ALP in liver extract of *Lepus townsendii*.

MATERIALS AND METHODS

Animal handling/chemicals

Five (5) male rabbits between 8 and 9 weeks old were obtained from the Experimental Animal House, Department of Biological
Preparation of liver extract of alkaline phosphatase

The extraction and purification of the liver enzyme was by the methods described by Malomo et al. (2003) and Arike et al. (2008), but with minor modifications. The rabbit was dissected and the liver carefully removed and washed in physiological saline solution. Two grammes (2 g) of the liver was homogenized in 40 ml of 0.1 M glycine-NaOH buffer (pH 9.9) solution. The homogenate was centrifuged in a Shermond bench centrifuge at 5000 x g for 40 min. The supernatant constituted the crude enzyme extract and was carefully harvested using a Pasteur pipette. To the supernatant, 4.17 M (NH₄)₂SO₄ was gradually added while stirring until 30% saturation was achieved. The solution was stored at 4°C for 1 h to precipitate the enzyme (Hulett et al., 1990). The precipitate was collected by centrifugation at 5,000 x g for 20 min and re-dissolved in 5 ml of 0.1 M glycine-NaOH buffer (pH 9.9) solution. The solubilized enzyme was subjected to dialysis at 2°C for 24 h to remove contaminating salt constituents (Qader et al., 2009), and further purified on a sephadex G-100 column to obtain a highly active ALP fraction. In total, ALP extracts from five (5) rabbits were used. Protein concentration was determined by the method of Bradford (1976) using bovine serum albumin as the standard. One unit of ALP activity (U) was expressed as 1 µM of 4-NP produced in the various tubes were interpolated from standard curves (not shown).

Inhibition studies using NaH₂PO₄ as inhibitor

The enzyme assay was carried out as described earlier. The glycine-NaOH buffer was substituted with 0.1 M glycine-NaOH buffer/2 mM NaH₂PO₄ mixture (2:1, v/v). Final concentration of inhibitor = 0.67 mM.

Effect of pH on enzyme activity

The activity of alkaline phosphatase was investigated under varying pH values of 8.4, 8.8, 9.2, 9.6, 9.9, 10.0 and 10.4 of 0.1 M glycine-NaOH buffer. A substrate concentration of 4 mM 4-NPP was used for the enzyme assay.

Effect of temperature on enzyme activity

The enzyme assay was carried out by incubating the enzyme mixture containing 4 mM 4-NPP in varying temperature values of 5, 15, 25, 35, 45 and 55°C.

Evaluation of kinetic parameters

The kinetic parameters were evaluated with the plot of the reciprocal of initial velocities (1/V) against corresponding reciprocal of substrate concentrations [4-NPP], that is, 1/V versus 1/[S] (Lineweaver and Burk, 1934).

Statistical analysis

The experiments were designed in a completely randomized method and data collected were analyzed by the analysis of variance procedure while treatment means were separated by the least significance difference (LSD) incorporated in the statistical analysis system (SAS) package of 9.1 version (2006).

RESULTS

The activity (V) of alkaline phosphatase measured in the
Figure 1. Double reciprocal plot of ALP assay in the presence of inhibitor NaH$_2$PO$_4$ ( ) and the control ( ) analysis. [I]: concentration of inhibitor = 0.67 mM.

absence and presence of inhibitor ([I] = 0.67 mM NaH$_2$PO$_4$) is represented by the Lineweaver-Burk plot (Figure 1). By inspection, the Lineweaver-Burk plot (Figure 1) showed that ALP activity was competitively inhibited by 0.67 mM NaH$_2$PO$_4$. Also, the plots representing the presence and absence (control) of the inhibitor intersected the x-axis at -1.1 and -2, respectively. Furthermore, the two plots converged at a common point of intersection on the y-axis: 5 x 10$^4$ µM$^{-1}$/min$^{-1}$. The kinetic properties of ALP deduced from the Lineweaver-Burk plot are summarized in Table 2. The activity of alkaline phosphatase investigated in varied alkaline pH environment is presented in Table 3.

Values are mean ± S.D of five (n = 5) determinations. Means in the rows with the same letter are not significantly different at p < 0.05 according to LSD. A cursory look at Table 3 shows that the activity of ALP exhibited two phase profile within the range of values of pH = 8.4 to 10.4. The first phase showed increasing ALP activity as pH values were adjusted from 8.4 to 9.2. Noteworthy, the pH value of about 9.2 corresponded to the maximum enzyme activity attained within the experimental pH range. Therefore, about pH 9.2 represented the optimum pH value of ALP extracted from *L. townsendii* liver. However, alkaline phosphatase activity at pH 10.0 was not significantly different (p < 0.05) from the activity at optimum pH. Further increases in pH values beyond the optimum engendered decreasing level of ALP activity.

The relationship between alkaline phosphatase activity and experimental incubation temperature of the enzyme assay is presented in Table 4. The pattern ALP activity in relation to changes in experimental temperature showed two phase profile. The results in Table 4 showed that the optimum temperature of alkaline phosphatase activity was about 45°C. The maximum enzyme activity attained at optimum temperature was 5.01 ± 0.56 µM/min$^{-1}$. Alkaline phosphatase activity at 35°C (4.67 ± 0.79 µM/min) was not significantly different (p < 0.05) when compared to activity at 55°C (4.53 ± 0.83 µM/min$^{-1}$). Using
Arrhenius plot, log V versus 1/T, the activation energy ($E_a$) of catalysis was evaluated thus:

$$\log V = E_a/2.3RT$$

where, $R = 8.31447$ J K$^{-1}$ mol$^{-1}$; molar gas constant. But gradient of plot is: -800 = $E_a/2.3R$. Therefore, $E_a = 15.23$ KJ mole$^{-1}$.

**DISCUSSION**

This study demonstrated the activity of alkaline phosphatase (ALP) in liver extract of *L. townsendii*. The occurrence and diversity of ALP in biological systems has been reported by several authors (Coburn et al., 1998; Zhang et al., 2004). For instance, Weissig et al. (1993) reported on sequence comparisons between different ALP indicated that about 25 to 30% homology exist between mammalian and *E. coli* alkaline phosphatase. Despite differences in amino acid sequences and three-dimensional structures, all ALPs catalyze the hydrolysis of almost any phosphomonoester with release of inorganic phosphate and alcohol. In addition, although ALP exhibits broad specificity for wide range of phosphorylated substrates, the enzyme displays variable affinity for these substrates depending on the molecular nature of the substrate, isofor and source of the enzyme. Szalewicz et al. (2003) noted that the equivalent enzyme and acid phosphatase of frog (*Rana esculenta*) liver displayed higher affinity for peptidic substrates than for small phosphate esters. Also, Coburn et al. (1998), from their findings stated that in the presence of pyridoxal phosphate as substrate, bovin kidney ALP $K_m$ was 0.42 ± 0.04 µmol$^{-1}$, whereas enzyme extracted from the intestine gave 1.6 ± 0.2 µmol$^{-1}$ and placenta gave 0.42 ± 0.08 µmol$^{-1}$. Comparatively, the present investigation showed that ALP liver extract of *L. townsendii* exhibited higher affinity for 4-NPP ($K_m = 0.5 ± 0.25$ mM) (Table 2) than enzyme extracts from rat (*Rattus novergicus*) kidney ($K_m = 6.41$ mM) (Arise et al., 2008) and human placental isoenzyme ($K_m = 5.55$ mM) (Saini et al., 2005). These findings serve to highlight and confirm the occurrence of isoforms of ALP amongst the mammalian genera.

More than five decades ago, Hilliard et al. (1965), demonstrated that endogenous phosphate interferes with the determination of ALP in urine and suggested that the wide variation in serum inorganic phosphate concentrations in diseases such as uremia or renal tubular disease might interfere with ALP measurements in serum. From inspection of the double reciprocal plot (Figure 1), $V_{\text{max}}$ of the enzyme was not altered in the presence of inhibitor. Therefore, the present kinetic studies showed that phosphate salt, NaH$_2$PO$_4$, is a competitive inhibitor of ALP activity. This finding is in accord with previous research reports by Fox (1978), Coburn et al. (1998) and So et al. (2007), in which they noted that ALP is competitively inhibited by physiological concentrations of inorganic phosphate. They further averred that inorganic phosphate is an important physiologic regulator of extracellular ALP activity. Incongruously, the possible effects of endogenous phosphate on phosphatase activity with natural substrates under physiological conditions have not been rigorously investigated (Coburn et al., 1998).

Although the pH of an enzyme often reflects the pH of its normal environment, the optimum value may not be precisely the same in every biological system. Noteworthy, as far back as five decades ago, Garen and Levinthal (1960), reported optimal pH for ALP activity of *E. coli* to be about 8.0, while the bovine enzyme optimum pH was slightly higher (8.5) (Harada et al., 1986). Furthermore, study of ALP from human hydatidiform by Aberomand et al. (2008), gave the optimum pH of 10.8. The current study reported optimum pH value of ALP liver extract of *L. townsendii* to be about 9.2. These findings are consistent with previous studies by Zappa et al. (2001), in which they observed that mammalian ALPs possess higher pH optima than procaryotes (*E. coli*) enzyme, and proposed that substitution of two amino acid residues with corresponding histidine molecules in the mammalian enzymes are responsible for this increase in
optimum pH (Holtz and Kantrowitz, 1999; Murphy et al., 1995). These variations in ALP activity which are consequences of adjustments in $K_m$ or $V_{\text{max}}$ values or both, suggest that pH/activity relationship of ALP may be a factor in the intracellular regulation of its activity.

Enzyme activity/temperature linked properties reported elsewhere (Suzuki et al., 2005; Lee et al. 2007; Copeland et al. 1985; Aberomand et al. 2008) defined the so-called enzyme “temperature optimum” of ALP activity. The present report suggests that at experimental temperature of about 45°C, ALP extract of *L. townsendii* exhibited maximum conformational flexibility to accommodate the substrate and enhanced conformational changes required for maximum catalysis. Contrary to the present suggestion, Daniel et al. (2001) proposed that “temperature optimum” is not an intrinsic property, which is derived from a complex mixture of both activity and thermal stability effects.

The Arrhenius plot (Figure 2) conformed to the pattern previously described by Copeland et al. (1985). They averred that all enzymes of human origin exhibited similar linear Arrhenius relationships with the range of 20 to 37°C with corresponding $E_a$ values between 30 and 36 KJmol$^{-1}$. In the present study, ALP activity exhibited linear Arrhenius relationship at values of temperature greater than 44.95°C with corresponding $E_a = 15.23$ KJ mol$^{-1}$ (Figure 2). Although ALP obtained from human and *L. townsendii* showed linear Arrhenius relation within variable temperature range, $E_a$ values of catalysis were significantly different. Again, in concord with the present investigations, studies by Copeland et al. (1985), reported that porcine kidney enzyme obeyed an Arrhenius relationship that was slightly but significantly different from the isoenzymes of human origin.
