Malaria a mosquito-borne protozoan infection is one of the health challenges facing majority of people living in sub-Saharan Africa including Nigeria (an endemic region). The causative agents Plasmodium species parasitizes host erythrocytes and destroys its hemoglobin thereby causing anaemia in some of the infected individuals. This study evaluated some haemostatic parameters of malaria parasitized subjects living in Owo-Ondo State. Haemostatic parameters (Prothrombin time (PT), Activated Partial Thromboplastin Time (APTT) and Platelet count) in 100 subjects, including 50 malaria-infected and 50 non-malaria infected, living in Owo-Ondo State, an area of malaria mesoendemic transmission in Nigeria were evaluated using standard operating procedure. There was a significant prolongation in PT and APTT in among the symptomatic group compared to the asymptomatic group (p< 0.05). There was a statistically significant decrease (p< 0.05) in the platelet counts of the symptomatic group compared to the asymptomatic group. Subjects infected with malaria parasites exhibited significant changes in some haemostatic parameters, thus inclusion of these parameters in malaria diagnosis could aid in patients’ treatment.

INTRODUCTION

Reports have showed that Vector borne diseases (VBDs) are posing threat to global health thus accounting for 17% of the global infectious disease burden and are responsible for substantial morbidity and mortality worldwide (London School of Hygiene & Tropical Medicine, 2021; Ramalho-Ortigao & Gubler, 2020; World Health Organization, 2020). Among the VBDs, Mosquito-borne infectious disease account for the majority of cases reported as well as mortality, and disability-adjusted life years. Malaria is one of the
mosquito-borne infection with high global burden (Franklino et al., 2019). Despite Nigeria Government intervention towards eradication of malaria, the country is still counted among endemic countries (World Health Organization, 2021). Children under the age of 5 years and pregnant women are the major group greatly affected by malaria infection (Oyibo et al., 2021; Oladimeji et al., 2019; Cohee & Laufer, 2018). The major route of acquiring the infection by human host is through the bite of infected female anopheles’ mosquito during their blood meal (Wells & Andrew, 2019). Transfusion transmission of Plasmodium species had also been documented (Alho et al., 2017; Allain, 2010; Owusu-Ofori et al., 2010), but less attention had been paid to this in endemic region (Allain, 2010). Though rare health workers needlestick injury and sharing of needles by drug addicts had been reported as another route of transmission of malaria infection (Minard et al., 2021; Alho et al., 2017; Chau et al., 2002; Weir, 1997). Another rare cases of malaria transmission is through congenital transmission, here parasitized erythrocytes can be transfer from infected mother to the fetus either transplacentally or during labor (Bilal et al., 2020; Omer et al., 2020; Olupot-Olupot et al., 2018; Sotimehin et al., 2008).

Alteration in haematological parameters had been documented as one of the major effects of malaria on human host (Al-Salaby et al., 2016; Osaro et al., 2014; Squire et al., 2014; Kayode et al., 2011; Maina et al., 2010; Wickramasinghe & Abdalla, 2000), the disease also altered some biochemical parameters as well (Al-Salaby et al., 2016; Kayode et al., 2011; Adeosun et al., 2007). Major study on malaria and its associated haemostatic parameter had been majorly on platelet count (Gupta et al., 2019; Peprah et al., 2020; Sakzubre et al., 2020), and when other parameter was done it is usually on pregnant women. In this study, changes in haemostatic parameters in symptomatic malarious and asymptomatic malarious subjects were compared. This is to asserting the possible effect of the presented symptom of malaria infection such as fever and raised body temperature on haemostatic parameters.

METHODS

Study area

This study was conducted in Owo-Ondo State. The town Owo, lies at latitude 7°10′59.988″N and longitude 53°4′59.988″E with an altitude of 360m. Owo is less dense town with an estimated population of about 276,593 (National Population Commission (2007). It is located within the low rain forest zone of Nigeria and has two seasons, dry and wet. The dry season lasts from mid-October to March while the rainy season lasts from April to September.

Study population

The study was conducted at Federal Medical Centre, Owo which serve as a tertiary institution in Ondo State. A total number of 100 samples were collected. Fifty (50) samples were collected from symptomatic malarious patients with signs and symptoms of malaria (this includes; headache, fever, malaise, chill, nausea, vomiting and body temperature above 37°C). Fifty (50) blood samples were also collected from apparently healthy subjects with no sign or symptom of malaria but stained thin film of their blood samples shows malaria parasites (subjects in this group are asymptomatic).

Clinical thermometer was used to determine the body temperature of all subjects. Subjects with symptoms such as headache, fever, malaise, chill, nausea, vomiting and body temperature above 37°C were grouped symptomatic while those without any symptom were grouped asymptomatic.

Inclusion criteria

Patients with sign and symptom of malaria and also positive to malaria parasitive testing using microscopy. This group serves as symptomatic malarious patients individual with no sign and symptom of malaria parasites served as asymptomatic malarious subject and their thin blood film were positive to malaria parasite.

Exclusion criteria

In Both groups of subjects, individual with liver disease such as Hepatitis-B and C infection or liver cancer were excluded. Patients on antimalaria drugs were excluded. Subjects without malaria parasites were also excluded from this study.

Specimen collection

About nine 9ml of blood was collected from each participants and 4.5 ml were dispensed into a pre-labeled bottle containing 1.5ml Sodium citrate. The remaining blood was dispensed into pre-labeled bottle of Ethylene Diamine tetra acetic acid (EDTA).

Sample Analysis

The blood samples were analysed within 4 hours of collection. Thin blood films were made for malaria parasite screening as described by Chesbrough (2006). Platelet count were analysed by diluting with ammonium oxalate and using standard manual methods (Chesbrough, 2006). While Prothrombin Time (PT) and Activated Partial Thromboplastin Time (APTT) were estimated using Calcium Rabbit Brain Thromboplastin and Kaolin platelet substitute mixture respectively (Dace & Lewis, 2001; Ramnik, 2009).

Statistical analysis of data
The mean values obtained from the control and test groups were recorded and compared statistically using the unpaired T-Test and Symmetric Measured Test of the Statistical Package for Social Sciences (SPSS).

RESULTS

A total of one hundred (100) subjects were involved in this study, comprised of fifty (50) symptomatic malaria patients and 50 asymptomatic individual without sign and symptom of malaria for two weeks. There was prolong in prothrombin time of malaria symptomatic patients compared to asymptomatic (Table 1, Figure 1). Activated Partial Thromboplastin time of the symptomatic patients was also found to be prolong when compared with asymptomatic subjects (Table 1, Figure 2). However, the Mean Platelet counts of the symptomatic patients was significantly lower (p<0.05) compared to asymptomatic group (Table 1, Figure 3). These results show that there was a significant difference in haemostatic parameters of symptomatic and asymptomatic malarious subjects.

DISCUSSION

Haematological and haemostatic abnormalities are considered hallmarks of malaria, and are reported to be most pronounced in Plasmodium falciparum infection, probably as a result of the higher levels of parasitemia found in these patients (Facer, 1994). The findings presented in previous study shows that in malaria, there are several peripheral blood changes, including anemia which is a common presentation and complicated malaria has been observed to be a consequence of Plasmodium falciparum infection (Mohapatra et al., 2013). In this present study, the effect of malaria on prothrombin time, Partial thromboplastin time with kaolin (PTTK), and platelet counts were considered.

The result of this study showed that malaria infection debilitates prothrombin time (PT) by causing prolongation in prothrombin time this is in line with Mohamed and Mubarak (2009) report. This effect therefore is an indication that malaria patients may have deficiency of factor I, II, VII and X when it is prolonged.

The result of this study showed that malaria infection debilitates partial thromboplastin time with kaolin (PTTK). This is line with findings of Erhabor et al. (2020) on pregnant women with malaria infection. This increase could be due to the effect of malaria parasite on clotting factors either directly or by affecting the hepatocytes which are responsible for the most of the clotting factors thereby, leading to prolonged bleeding in the patients with malaria parasite (Lillicrap et al., 2009). This disorder of coagulation factors could lead to an increased risk of bleeding (haemorrhage) or obstructive clotting (thrombosis) (Lillicrap et al., 2009).

Previous study revealed that patients with malaria had low platelet count (Abro et al., 2009). In their report most of the patients had mild thrombocytopenia (Abro et al., 2009). A study carried out in Pakistan showed that overall, of malaria patients were found to have low platelet count (Sheraz et al., 2008). Malaria is usually associated with various degrees of thrombocytopenia (Sheraz et al., 2008). The result of this present study also supports the earlier claim by Horstmann et al., (Horstman & Dietrich, 1985) who reported that malaria infection has an adverse effect on platelet count. Similar result had also been reported earlier in previous studies that patients with malaria had low platelet count (Abro et al., 2009). Role of platelet in malaria parasite sequestration had been documented (Rowe et al., 2009), the interaction of Plasmodium falciparum infected erythrocytes affects platelets hence cause platelets clumping (autoagglutination) (Miller et al., 2002). In a review, suggestion had been made that oxidative stress might responsible for part in the pathogenesis of thrombocytopenia associated to malaria (Percário et al 2012).

CONCLUSION

This study revealed that malaria parasite debilitates haemostatic parameters by prolonging the prothrombin time (PT), Activated Partial Thromboplastin Time (APTT) and reducing platelet counts. Future study will investigate liver function in malaria infected patients in order to ascertain if the
