Accepted 28 March, 2011

Eight microsatellite loci were isolated using an enrichment protocol from *Ericerus pela* Chavannes, representing the first microsatellite loci available for the white wax scale. All loci were polymorphic within *E. pela*. Allele numbers range from six to eleven with the observed heterozygosity (Hₒ) ranging from 0.0000 to 1.0000. These primers screened in this study provide a foundation for population genetic studies of the white wax scale.

Key words: Microsatellite marker, white wax scale, population genetic.

INTRODUCTION

The Chinese white wax scale is a famous resource insect of China, the wax secreted by the scale was widely used in wax candle production, wax printing, engraving print and Chinese medicine in China about one thousand years ago, while it is now been used in chemical, pharmaceutical, food and cosmetic industry (Chen and Feng, 2009). Because of wax large application, the study of the scale secreted wax become more and more important. The white wax scale widely distributed in most parts of China, Japanese and Korea peninsula from subtropics region (north latitude 24°) to temperate region (north latitude 44°) and formed different geographic populations adapting to different climate (Long, 2004; Wang and Xu, 2006; Chen and Feng, 2009). Such adaptation has a strong impact on the genetic variation among populations (Chen et al., 1998). For population genetic analyses and breeding studies of the white wax scale, it is important to isolate and characterize its microsatellite loci.

MATERIALS AND METHODS

Microsatellite-containing DNA fragments library construction

Genomic DNA was isolated from a single *Ericerus pela* female adult individual following the ‘proteinase K’ protocol described by Tian (1999). DNA was digested with Rsal restriction enzyme (TaKaRa) then ligated to 21 linker (5'-CTCTTGCTTACGCGTGGACTA-3') and 25 linker (5'-phosphate-TAGTCCACGCGTAAGCAAGAG-3'). The enrichment procedure was followed by the protocol from Glenn and Schable (2005) and Franck et al. (2005) based on Streptavidin MagneSphere (Ivitrogen) with slight modifications. 5'-biotinylated (CT)₁₀ and (GT)₁₀ oligonucleotides were used as probes. The enriched single strand DNA was amplified by PCR (polymerase chain reaction) using *Rsa*₂₁ linker as primer to recover double-stranded DNA. The 250 to 1000 bp PCR fractions were selected on an agarose gel, purified, and ligated into pMD18 - T vector (TaKaRa). The plasmids were further transformed into *Escherichia coli* competent cells (Tiangen).

Microsatellite loci sequencing, primer design and evaluation

About one hundred recombinant clones propagated in LB/ampicillin medium were selected at random and sequenced by Huada Genetics Company. A total of 31 sequences contained clear repeated units (di, tri and tetranucleotide). Following primers were

*Significant departure from HWE.

designed for these sequences using Primer 3 online.

To evaluate the polymorphism of the primer pairs designed, 24 *E. pela* individuals collected from *Ligustrum lucidum* trees in a greenhouse in Kunming were used. PCR reactions were carried out in 10 µl reaction volumes containing 1×PCR buffer, 2 mM MgCl<sub>2</sub>, 0.2 mM dNTP, 1 U Taq DNA polymerase (TaKaRa), 0.5 µM each primer and 0.5 µl DNA template. For all tested primers, thermal cycling conditions were carried out as follows: 4 min at 94°C, 30 cycles were performed consisting of 45 s at 94°C, 45 s annealing (Table 1 shows annealing temperatures) and 30 s extension at 72°C, with a final extension step at 72°C for 10 min. PCR productions mix with GelRed (Biotium, America) were separated on 8% denaturing polyacrylamide gels.

Observed heterozygosity (H<sub>O</sub>), expected heterozygosity (H<sub>E</sub>) and significant deviations from Hardy-Weinberg equilibrium (HWE) were calculated using POPgene 1.32 (Yeh et al., 2000). Linkage disequilibrium (LD) and frequency of null allele were tested using GENEpop 4.0 on the web.

**RESULTS AND DISCUSSION**

Among the primer pairs tested in this laboratory
population, eight were polymorphic and two were monomorphic. Summary data for the eight characterized polymorphic loci are presented in Table 1. These data revealed that observed heterozygosity of all loci (HO) varied between 0.0000 and 1.0000. HO of four homozygous loci were 0.0000, and two heterzygous loci were 1.0000. These homozygous/heterzygous loci departure from Hardy-Weinberg equilibrium significantly could be due to sampling bias (E. pela individuals collected from only one isolated greenhouse). Perhaps no genetic linkage between these loci, homozygote and heterozygote were kept in the greenhouse) and unknown founder relatedness in the semi-free population. We compared the results of E. pela to other species (Vuuren, 2006; Miao et al., 2008; Lavandero and Dominguez, 2010; Zou et al., 2010), such as Platyscapa awekei (common deviation from HWE due to inbreeding), Eriosoma lanigerum (small proportion of loci deviating from HWE due to null alleles), Grus japonensis (sampling bias and unknown founder relatedness) and Taxus yunnanensis (most loci significantly deviated from HWE due to a large heterozygote deficiency). Expected heterozygosity (HE) of the eight loci range from 0.7872 to 0.9087. No significant LD was detected among the eight loci. These primers were used in other geographic populations of E. pela successfully.

In conclusion, we report the isolation of eight microsatellite DNA loci which are useful for population genetic analyses of the E. pela. Further studies using these primers should allow a better understanding of phylogeographic relationships and the origin land of the white wax scale.
