Receive 2 July, 2016, Accepted 9 August, 2016.

A study was undertaken along land use gradients with different soil types in subtropical ecosystem of Northern India to evaluate the accuracy of arbuscular mycorrhizal fungi (AMF). The gradients was from natural land with forest tree, farmer’s field under chemically managed, farmer’s field under organically managed and Industrial wasteland with five different plant species. We investigate the total AMF species in land use system of different soil types and also in trap culture set from same land use system. Distribution of mycorrhizal species were calculated directly by quantification AMF spores and indirectly by sequencing the SSU-ITS and LSU regions of rDNA. A total 19 AMF morphotypes from direct field sampling and additional 35 morphotypes from trap culture were recovered, which represented seven genera and eighteen species. Result suggested that few Rhizophagus and Funneliformis species came from organically managed and natural land; most of the species came from sites representing chemically managed and industrial wasteland sites from which Gigaspora and Scutellospora species were absent. Organically managed land contributed the largest number of AMF species and diversity, even more than those found in natural sites, which suggests that factors contributing to the diversity of AMF are indeed complex: For example, chemically managed sites not only causes loss of fungal biodiversity but also selectively favors smaller spores of genera Rhizophagus and Funneliformis.

Key words: Tillage, diversity, ribosomal dna, raised bed plantation, arbuscular mycorrhizal (AM), morphotypes.

INTRODUCTION

Arbuscular mycorrhizal fungi (AMF) form mutually beneficial associations with a large number of terrestrial plant species (Van der Heijden et al., 1998). These fungi promote phosphorous uptake and help plants in coping with different forms of stress. Communities of AMF are affected by many factors including plant genotype, agricultural practices, and pollution (Sander et al., 1995a). Farming practices such as intensive cultivation,
tillage and using sewage sludge as soil amendment may affect communities of AMF both qualitatively and quantitatively (Sieverding, 1990). More report by Jansa et al. (2003) observed that Rhizophagus species were dominant in highly tilled field, whereas Scutellospora species were prevalent in low tillage fields. Furthermore Treseder et al. (2004) observed that conventional agricultural practices such as application of chemical fertilizers and tillage intensity tend to decrease AMF spore abundance and alter community composition. Moreover Gaur and Adholeya (2002) suggested that application of low input fertilizers (Organic) promotes the growth of indigenous AMF in nutrient-limited soils. Only a few studies have explored the extent to which soils under conventional and organic farming systems in the temperate zone differ in terms of the composition and species richness of AMF (Oehl et al., 2003; Hjiri et al., 2006). There are 102 AM fungi reported in tropical diverse habitats from India (Manoharachary et al., 2005). The occurrence of AM fungi in a forest and coastal regions of Andhra Pradesh reported by Manoharachary et al. (1991), distribution and identification of AM fungi in the rhizosphere soils of the tropical plains collected from Tamil Nadu, India by Ragupathy and Mahadevan (1993) and natural forest regions in the Old Delhi Ridge, Saraswati Range of Haryana by Thapar and Uniyal (1996). However, most of study surveyed AMF diversity in the subtropical region of Northern India based on morphological charcters of spores collected from single land use system (Karthikeyan and Selvaraj, 2009; Kumar and Grampalli, 2010). The comprehensive survey of land use intensity and different soil types strongly affect the AMF community composition in temperate soil earlier reported by Oehl et al., 2010; Stover et al., 2012; González et al., 2012; Bainard et al., 2015). Subsequent study by Dobó et al. (2016) were recorded 29 AMF morphospecies, belonging to nine genera originated from the rhizospheric soil of the three land uses system. However rich diversity of AMF found over a broad range of different land use (Cropping vs noncropping) in tropical soil, to our knowledge, has not been investigated so far using multiple methods.

Therefore aim of the present study was to investigate AMF diversity in different land use and soil types in tropical soil. It was hypothesized that AMF are more abundant and diverse in organically managed as well as natural soils than those in chemically managed soils and in soils affected by industrial pollution. Hypothesis was tested directly by quantifying the number of spores and species richness and indirectly by sequencing the SSU-ITS and LSU regions of rDNA. To determine AMF diversity, the following seven land-use systems from four agroclimatic zone with different soil types were selected: Agriculture land high-intensity farming (Chemically managed), Agriculture land under conventional tillage (ConT), Agriculture land under Zero tillage (ZTL), organic (low-input) farming, agricultural field highly contaminated tannery effluent, and natural land (NAL).

### MATERIALS AND METHODS

#### Sampling site

The investigation was carried out in seven different land use pattern (Table 1). The annual rainfall range 800 to 1200 mm and has ample irrigation resources. The first agroclimatic zone near Ghaziabad (28° 40’ N, 77° 28’ E) which is part of the western plains of Uttar Pradesh, India constitutes the sub-humid zone. The second agroclimatic zone near Palwal (28° 9’ 0” N / 77° 20’ 0” E), in eastern zone of Haryana, India. The third sampling agroclimatic zone near Pachmari (22° 28’ 0” N / 78° 26’ 0” E) was part of the Malwa plateau zone of Madhya Pradesh which has medium black sandy soil. The fourth agroclimatic zone sampling was Kanpur

(80°21′ N / 20°38′ E) part of the central plains of Uttar Pradesh, India constituted sub-humid zone.

**Sampling of AM fungi**

All soils were sampled in 2008 in October from seven land use system of four agroclimatic zone. Each sample collection point was divided into four blocks. Undisturbed core samples 20 soil cores/plot were collected (soil and roots) from the rhizosphere of wheat plants from a depth of 0 to 30 cm using core sampler. Thus, a total of 80 soil cores were collected from each collection site. The samples were air dried in the shade to a point where there is no free moisture and were placed into zipped bags, and stored at 4°C in a cold room until processed. The samples were used for three different purposes: (i) Propagation of AM fungal isolate of each collection point for their identification; (ii) Analysis of AM fungal parameters; and (iii) Analysis of soil chemical parameters.

**Physical and chemical analysis of soil**

A soil suspension of 1:2.5 (soil-to-water mixture) was made. The pH of the soil suspension was measured by digital pH meter (Expandable Ion Analyser EA 940, Orion Research) and the electrical conductivity was measured by digital electrical conductivity meter (Controlled dynamics). A protocol by Datta et al. (1962) was followed for measuring % organic carbon. % Total nitrogen was calculated using Kjeldahl’s method by Bremner (1960). Available phosphorus was determined using Olsen’s method (Olsen et al., 1954) and the estimation of available potassium was done using flame photometer with filters (Wood and Deturk, 1940).

**Trap cultures**

Mycorrhizal fungi obtained from different land use system tropical soil are very difficult to identify even impossible to identify up to species level. This is due to tropical environments (high temperature, moisture) and those with high organic matter as well as high proportion of spores undergo so much structural changes or degradation. Therefore, pot culture established in year 2008 using soil samples to recover spores from AM fungal species present in field soil, including some of which may not have sporulated at time of sampling. The trap cultures were established using methodology described by Oehl et al. (2003). Plastic trays (460×290×240 mm³) were used to establish AM fungal cultures in greenhouse using soil samples from all collection sites. For each collection site, four trays (comprising four blocks) were prepared. The plastic trays were provided with 50 mm hole at the bottom. A 20-mm thick drainage mat (Enkadrain ST, Schoellkopf AG, CH-8057 Zurich, Switzerland) was placed at the bottom of the tray and the tray was filled with 25 Kg of substrate (50% Terragreen: American aluminium oxide, oil dry phosphorus iii) and 50% soil sediment: Nutrient deficient (Olsen P = 1.56 ppm; Organic C = 0.28%; Total N = 0.052 %; K = 52.66 ppm). The substrate was autoclaved at 120°C for one hour at 15 psi before filling. Substrate cores (50 g) were taken out from five different places in the tray and were replaced by five, undisturbed soil cores (50 g, containing collection site’s AM fungi) to inoculate the hosts. Seeds of *Allium cepa*, *Tagetes sp.*, *Daucus carota*, *Medicago sativa* (alfalfa), and *Trifolium alexandrianum* (barseem) were pregerminated. Five pre-germinated seeds of each species were placed at the top of all five soil cores. The plants were watered to a moisture level of approximately 60% of the water holding capacity and were grown in greenhouse at 20 ± 5°C with 60% relative humidity. The pots were arranged on a greenhouse bench in a completely randomized design with 4 replications. Half-strength Hoagland’s nutrient solution (Hoagland and Arnon, 1938) was provided to the plants at fortnightly interval. After four months of growth cycle, the pots were left to drying undisturbed with a fairly stable temperature so that the drying period is not too rapid. After completion of the growth cycle the dried shoots were cut at the ground level without disturbing the substrate and seeds of different hosts *Gossypium*, *Vetiver*, *Vigna radiate*, *Sorghum* and *Tagetnus sp.* were sown again. Three trap culture cycles were propagated. After each cycle, rhizosphere soil cores were taken from the vicinity of trap plants at a depth of 0 to 15 cm and species characterization was done.

**AMF spore identification**

Spores were collected separately and similar looking spores were grouped into different spores morphotypes according to colour, size and mycelial attachment with spores. Permanent slides was prepared in polyvinyl alcohol and polyvinyl alcohol plus Melzer’s solution (1:1) as described by Walker and Trappe (1993). Spores from each morphotypes were observed under a Zeiss compound microscope equipped with a digital imaging system, and digital photographs was taken with a Zeiss Axiacam RTC (Germany). Spore diameter, wall thickness and hyphal thickness were measured using software Axio Vision (Version 4.7) attached to the microscope. The diagnostic slides of different species of AM fungal spores were prepared and features of the spores morphology were compared according to current taxonomic criteria (Schenck and Perez, 1990) and also using the internet information from the INVAM website (http://www.invam.cat.wvu.edu).

**Data analysis**

Spores were washed with distilled water and evenly over the entire grid. They were counted under a stereoscopic microscope (40×). The number of spores was expressed as the mean of four replicates. Diversity of AM fungi in four study sites was evaluated by observing the spores in four replicates each of 100 g of soil. Once the data were obtained, the following were calculated for AM fungal diversity analysis (1) Spore density (Total number of spores was expressed in mean of four replicate in 100 g of soil sample) (2) Relative Spores abundance = Number of given species spore/Total number of spores × 100 % (3) AM fungal species richness was measure known as $d = s/N$ where s equals the number of different AMF species in site, and N equals the total number of individual organisms in site (4) Shannon–Weiner diversity index index (H') of AMF spore morphotypes was calculated for each sites with equation $H' = - \sum (Pi) \ln (Pi)$. $Pi = ni/N$ (ni is the number of individuals of species i, and N is the total number individuals in all species). Species diversity (Shannon–weiner index) in each experimental trap culture were used in one-way ANOVA with soil treatment as a factor with seven levels an four replicates of the trap cultures for each treatment. All analyses were performed in JMP version 5.1.1 (SAS Institute Inc., Cary, North Carolina, 1989-2002), and differences between the means were analyzed using Tukey HSD multiple comparisons with P <0.05. Similarity index (Legendre and Legendre, 1998) was calculated to compare the similarity of species among different sites as based on $x^2$ distance using ward’s minimum variance methods. The correspondence units (dimensionless) on the basis of spore number per 100 g of soil.

**Molecular analysis**

A single spore from each morphotype was transferred aseptically to eppendorf tube containing 10 μl of 10X PCR buffer (Invitrogen, USA) and used for DNA extraction. The spore was crushed, 10 μl of 20% Chelex resin added immediately, and the tube centrifuged

RESULTS

The soil types varies range black medium texture alluvial soil to gangatic alluvial soils and pH was found to be slightly basic (7.18-7.71) in all the sites. The soil organic carbon was highest in industrial waste land (IWL) and lowest in the chemically managed land (CML). The available phosphorus ranges between 4.95 and 37.75 ppm and it was highest in the industrial wasteland sites than the other sites (Table 2).

Based on the classification of *Glomeromycota* reported by Schüller and Walker (2010), the ten species of AMF were recorded in the field soil and eight additional species of AMF observed in the trap soil. At the genus level, *Rhizophagus* was dominant AMF species. The most common species sporulating in trap cultures set up from soils all the sites were *Rhizophagus irregularis* and *Rhizophagus intraradices* (Table 4). Mycorrhizal spores density differed significantly among trap cultures set up from both managed and natural ecosystem (Figure 2). Highest number of mycorrhizal spores was present in zero tillage land (ZTL) and lowest in natural land (NAL) showed in Figure 2. However species richness was decrease in order of ORG>NAL>ZTL>RBP>CML>ConT and the AMF species diversity as expressed by the H’ decrease in the order of ORG<RBP>NAL>ZTL>IWL>CML>ConT (Table 3). The H’ value was greater in trap culture originated from ORG field and lowest in trap culture originated from Conventional tillage soil (ConT) (Table 3). Moreover relative spores abundance of *Gigaspora* and *Scutellospora* species were found more among trap cultures set up from both organically managed and natural ecosystems and some were restricted in their occurrence (Table 4). Similarity index based on cluster analysis showed that the highest similarity of AMF species composition between the sampling sites of ORG, RBP, NAL and ZTL on the other hand between sampling sites of IWL and CML (Figure 3).

Diversity in the Industrial wasteland soil

Spores of AMF collected from trap cultures originated from gangatic alluvial soils contaminated with tannery sludge were classified into 08 spores morphotypes all of these belonged to the genus *Rhizophagus*. Spores of these genera appeared yellow to reddish brown in reflected light and were globose to subglobose, 60 to 130 µM in diameter, although more than 75% of them were intermediate in size (80 to 100 µM).
Diversity in natural and organically managed land

Spores of AMF collected from trap cultures originated from medium black soil and medium texture alluvial soil under organically managed and natural land respectively were classified into 8 spore morphotypes, 5 of which represented the *Rhizophagus* species and 3 represented *Gigaspora*, *Scutellospora*, and *Acaulospora* species (Figure 1). Spores abundance of *Scutellospora* species were more in trap culture originated from natural sites as compared with under organically managed sites whereas *Gigaspora* species were more predominant in trap culture established from organically managed land (Table 4).

Diversity in chemically managed land

AM spores morphotypes collected from field and trap cultures consisted of entosols of alluvium soil under intensive cultivation, which had received chemical fertilizers; fell into six spore morphotypes, representing four taxa of the Glomeraceae on each from *Gigasporaceae* and *Acaulosporaceae* and one from the *Sclerocystis*. Glomeraceae spores significantly more dominant in trap culture set up from ConT field than in trap culture originated from RBP and ZTL field (Table 4).

**Molecular analysis**

All 35 morphotypes of AMF collected from the trap cultures were used for molecular analysis; of these, 11 Glomeraceae morphotypes were used for SSU-ITS rDNA analysis and 17 Glomereaceae, 6 *Gigasporaceae* and 1 *Acaulosporaceae* morphotypes for LSU rDNA analysis. The sequencing reaction was performed on PCR/nestedPCR/plasmid of 35 morphotypes of AMF; 39 sequences of n-rDNA consisting of the SSU-ITS and LSU regions were isolated from the sequence analysis. Out of the 39 sequences, 36 appeared homologous with known Glomeromycota whereas the remaining three did not show any degree of homology with Glomeromycota. Neighbor joining (NJ) analysis using 11 SSU-ITS rDNA sequences obtained from 11 AMF morphotypes including...
Figure 1. Spores of arbuscular mycorrhizal fungi isolated from trap culture originated from organically managed soil. (a) *Rhizophagus* sp. morphotype PALF1 in PVLG + Melzer reagent, (b) *Rhizophagus* sp. morphotype PALF2, (c-e) *Funneliformis coronatum* morphotypes PALF2AM1 in PVLG + Melzer reagent, (f) *Gigaspora margarita* of morphotypes PA16AM2 in PVLG + Melzer reagent, (g-h) *Gigaspora margarita* of morphotypes PA13AM1 in PVLG + Melzer reagent, (i-l) *Acaulospora* species M38AM1 in PVLG + Melzer reagent, (m-p) *Scutellospora* sp. of morphotypes PA13 in PVLG + Melzer reagent. those retrieved from GenBank grouped all of them into a single major cluster of Glomeraceae (Figure 4). Sequences obtained from 09 AMF morphotypes formed a subcluster (*Rhizophagus*) along with reference *R. irregularis* n-rDNA sequences obtained from GenBank. On the other hand, sequences obtained from 2 morphotypes fell in a clade of known *Funneliformis mosseae/Funneliformis coronatum* with 94% bootstrap support (Figure 4). Out of the 24 morphotypes subjected to LSU n-rDNA analysis, 13 Glomeraceae isolates were identified by the nested *Rhizophagus* primer pair 28G1(F) + LSURK7r (R) and 11 by the *Glomeromycota* primer pair FLR3 + FLR4 (R). Two phylogenetic trees were generated using the sequences obtained from two different sets of primer pairs (Figures 5 and 6). The NJ tree obtained from the 13 sequences obtained from *Rhizophagus* and *Funneliformis* morphotypes with known Glomeraceae sequences retrieved from GenBank showed a single major cluster of Glomeraceae (Figure 5). Out of the 13 sequences, 05 were grouped with a known *R. intraradices* and 06 with *R. irregularis* clade and 02 with the reference *Septoglomus deserticola* sequence with 100% bootstrap support (Figure 5). The NJ tree obtained from the 12 sequences generated by the
**Glomeromycota** primer along with reference sequences retrieved from GenBank showed three major clusters, one each of Glomeraezae, Gigasporaceae, and Acaulosporaceae (Figure 6). Out of these 12 sequences, 2 were grouped with Rhizophagus proliferus, 1 with Funneliformis mosseae, and 2 with known Funneliformis coronatum retrieved from GenBank. Sequences obtained from 7 Gigasporaceae morphotypes clustered with known Gigasporaceae retrieved from GenBank (Figure 6).

**DISCUSSION**

Previous report on distribution of AM fungi across a gradient of land use system in India mainly based on the morphological charcters of spores collected from field soil (Lakshmipathy et al., 2012; Bordoloi et al., 2015). The study present intervention using AMF morphotype collected from rhizospheric soil of field as well as trap culture to detect wide AMF diversity. The report by Bordoloi et al. (2015) suggested affect of mycorrhizal fungi in different landuse systems (Seven land use ecosystems of Arunachal Pradesh in Eastern Himalayan, India). However current investigation explore more under different land use systems in the tropical soil differ in terms of the composition and species richness of AMF. Moreover earlier surveys of populations of AMF, using either molecular or morphological approach, have focused on mycorrhizal roots (Helgason et al., 1999; Daniell et al., 2001) collected from field sites, and most
studies of the diversity of AMF have used only rDNA as a marker. However present study using single spore DNA extracts, followed by nested PCR approach based on sequencing of LSU and SSU-ITS region of rDNA was further complemented method towards comprehensive detection and characterization of AM fungi in environmental soil (Kumar et al., 2013).

In the study, 18 mycorrhizal species were identified from field as well as trap culture in different land use system. Diversity of AM fungal species in present study is lower (35 species) than reported by Muthukumar and Udaian (2000) from seven different ecosystem of Western Ghat, India. Present study showed many additional species of AMF, for example group of sporocarpic fungi recorded in sorghum trap culture. However sporocarpic fungi were not detected in field soil because its induced sporulation during intensive cultivation in trap cultures. Similarly by Oehl et al. (2003), group of sporocarpic fungi were recorded in trap culture and suggested that the species thus undetected in field samples had initiated sporulation in trap cultures. Hence present study identified different species of mycorrhiza not only using direct field sampling but also through trap culturing so that cover all missing taxa of AM fungi. In addition, our study recorded S. deserticola, R. proliferus, R. irregularis and R. intraradices of Glomeraceae from industrial wasteland site. Four unidentified species of *Rhizopagus* were recorded from the field soil polluted with tannery sludge by Khade and Adholeya (2009). Our study suggested low specis diversity mainly *Rhizopagus* species in industrial wasteland soils due to higher pH level (7.71) and high precipitation. Moreover availability of more amount of organic carbon and phosphorus in the contaminated soils may be another factor which might have affected the growth of mycorrhizal mycelium and hence reduced the species diversity. However in contrast
study by Raman and Sambandan (1998), Gigaspora and Scutellospora were also observed in soil contaminated from Tannery effluents. In present investigation S. deserticola was recorded from this site may also be metal tolerant tolerant since it survived under given condition naturally. Recent studies by Arias et al. (2010) showed effect of metal observation when Prosopis juliflora was inoculated with S. deserticola.

In the study, Shannon Wieners diversity index in chemically managed land shows significantly low (0.63) than organically managed and natural forest land (Table 3). A similar result was suggested by Sharmah and Jha (2011), who reported that mean spore density of AMF was significantly lower in disturbed forests land as compared to the slash-and-burn fields of Karbi Anglong Hill district of Assam. Spore density and species richness were significantly more in natural savannas than cultivated soil and lowest in intensively managed cotton soil of West Africa (Tchabi et al., 2008). Moreover most of ribosomal rDNA sequences obtained from this site clustered with known R. irregularis (Figures 4 to 6). Similar study using molecular methods by Mathimaran et al. (2005) found that R. intraradices was the dominant species of AMF in soils under conventional farming practices and suggested that, as with temperate ecosystems, addition of chemical fertilizers may dramatically decrease the availability of propagules of AMF in tropical soils. In contrast, study by Gai et al. (2006) recorded higher diversity index in the agricultural field. Present study relative spores abundance of genera Gigasporaceae were recorded low in chemically managed soil under intensive cultivation (Table 4).
Figure 6. Sequences generated from amplicon of primer set (FLR3+FLR4) used for phylogenetic analysis. Neighbor joining tree obtained from alignment of 12 LSU rDNA (400 bp from 5’ end) used in this study including 50LSU n-rDNA sequences retrieved from GenBank with (Mortierella polycephala) as an out-group. Percentage bootstrap support (out of 1000 replicates) is indicated. Names followed by accession no. represent sequences retrieved from GenBank. Names preceded by a shape represent the Sequence obtained in this work.

Furthemore, none of AMF morphotypes originated from chemically managed soil was clustered with genera Gigasporaceae (Figures 4 to 6). The present study supports earlier hypothesis by Jansa et al. (2003), suggested significantly lower Gigasporaceae species in chemically managed soils. It was also reported by Johnson (1993) that application of inorganic fertilizers (High input) increased the abundance of R. intraradices, whereas other species like Gigaspora gigantea, Gigaspora margarita, Scutellospora calospora or Paraglomus occultum disappeared. Recent investigation by Mirás-Avalos et al. (2011) based on denaturing gradient gel electrophoresis (DGGE) sequencing found that increased presence of Glomus fungi in agricultural soil under conventional tillage practices. Shannon-Weiner diversity index were significantly more
in trap culture set up field soil of raised bed plantation (RBP) and zero tillage (ZTL) soil (Table 3). Subsequently, sequencing of LSU rDNA also revealed that Gigaspora and Acaulospora species were present in RBP and ZTL sites respectively (Figures 5 to 6). Most of the AM fungal species that occurred in the RBP and ZTL do not occur in the other sites as the species cannot endure high degree of disturbances. Diversity index and species richness was more in organic and natural sites, a finding in line with the report by Gosling et al. (2010), who found that long-term application of organic manures results in rapid build-up of diverse range of AMF taxa. Higher species richness in organic and natural land than the other sites due to higher diversity of host plant and sites have higher soil organic carbon that is more suitable for AM fungal growth (Bordoloi et al., 2015). Higher similarity index of species composition between chemically managed site with Industrial wasteland site may be due to lower tree diversity exists in both the site (Figure 3). Disturbance produce in the agriculture land is well known to all which not only suppress the plant diversity but also the microbial community that exists in association with them. Studies by Brokaw (1985) suggested that disturbance inhibit competitive interactions and minimize dominance of species, maintaining species diversity and richness.

Conclusion

Study revealed diversity of mycorrhizal fungi significantly affected by the different farming practices. The study provide lists of AMF species present in different soil type and land use system of subtropical soil and also provide data with which further studies can be compared. The result of our finding indicate that AMF diversity in organically managed soils was higher because of organic sources of nutrients such as farmyard manure and compost do not suppress sporulation of Gigasporaceae. Now recent advancement of next generation sequencing may provides more complete picture of distribution of arbuscular mycorrhizal fungal communities in different land use system especially to understand association of AM fungi with rare and endangered plant species as well as the medicinal plant species widespread in the tropical forest soil.

Conflict of Interests

The authors have not declared any conflict of interests.

ACKNOWLEDGEMENTS

Authors thank the University Grants Commission of the Government of India for the award of a senior research fellowship to carry out doctoral work at The Energy and Resources Institute, New Delhi. This research was supported by funds provided to TERI by the Department of Biotechnology, Government of India.
