Glucocorticoid-induced diabetes mellitus (GIDM) is an abnormal increase in blood glucose associated with the use of glucocorticoids in a patient with or without a prior history of diabetes mellitus. This is a common and potentially harmful problem in clinical practice, affecting almost all medical specialties, but is often difficult to detect in clinical settings. The objective of this study was to determine effect of *Parkia biglobosa* extract on open wound healing in dexamethasone induced hyperglycaemia. Effect of three different doses of *P. biglobosa* extract (25, 50 and 100 mg/kg body wt.) for 14 consecutive days on open skin wound healing before and after dexamethasone-induced hyperglycaemia was investigated; histological assessment was also conducted on the fourteenth day. The three different doses of *P. biglobosa* extract decreased the serum glucose concentration in pre and post-treatment dexamethasone-induced hyperglycaemic animals; the percentage reduction was greater in the 50 and 100 mg/kg of *P. biglobosa*-pretreated groups (14.9 and 19.21%, respectively) as compared to that of ketoconazole, where it was only 16.5%. In the post treatment groups, the percentage reduction was greater in 100 mg/kg of *P. biglobosa* (17.7%) as compared to that of ketoconazole, where it was only 16.6%. Histological evaluation showed that the pretreated group of animals had higher performance scores on the grading scale and improved healing when compared with the post-treated groups. There was a demonstrable reduction in the wound healing process in the pre-treatment group that was dosed dependent.

**Key words:** *Parkia biglobosa*, open skin wound healing, dexamethasone-induced hyperglycaemia, histological assessment.

**INTRODUCTION**

Glucocorticoids are potent anti-inflammatory and immunosuppressive drugs which are widely used to treat a wide range of diseases. A number of side effects, including new-onset hyperglycaemia in patients without a history of diabetes mellitus (Suh and Park, 2017), also severely uncontrolled hyperglycaemia in patients with...
known DM is also associated with them. There are two main models, that is, incisional and excision for determining three basic phases in wound healing process (inflammation, proliferation, and maturation) (Dorsett-Martin, 2004). These are simple and reproducible models which represent basic requirement assessing the effects of different external factors on skin wound healing (Regan and Barbul, 2011). The incisional (sutured) skin healing model is used for wound tensile strength measurement (Davidson, 1998) while the excisional model is more appropriate for histological evaluation due to significantly broader morphological changes which occur during the healing process. Corticosteroid induced diabetes otherwise called steroid diabetes; the most common glucocorticoids which cause steroid diabetes are prednisolone and dexamethasone. It is also a simple and inexpensive model of a complex wound healing impairment (Gal et al., 2008). The excess of either endogenous or exogenous glucocorticoids has been shown to increase gluconeogenesis and decrease tissue glucose uptake, thus resulting in hyperglycaemia, potentially inducing diabetes (Wolfsheimer, 1989).

_Parkia biglobosa_ (Jacq.) R.Br. ex G. Don (family Fabaceae) popularly known as the “African locust bean tree”, it is a medium-sized tree growing up to 30 m in height. The plant is reported to contain carbohydrates, proteins, fats, minerals, vitamins, tannins and flavonoids. _P. biglobosa_ have been used in Nigeria and other West Africa in rural communities to treat variety of diseases as diabetes mellitus, malaria and pains. The hypoglycaemic effect of fermented seeds of _P. biglobosa_, a natural nutritional condiment that features frequently in some African diets as a spice, was investigated in alloxan induced diabetic rats (Builders, 2014).

Therefore, the aim of this study was to establish the effect of extract of _P. biglobosa_ on an excisional model of skin wound healing in normal healthy and corticosteroid treated as well as to evaluate the effects of various external factors on wound healing semi quantitative assessments.

**MATERIALS AND METHODS**

**Source of plant material and identification**

The stem barks of _P. biglobosa_ were collected from Chaza village in Niger State and the stem barks were identified by a taxonomist Mallam Muazam of the Department of Medicinal Plant Research and Traditional Medicine of National Institute for Pharmaceutical Research and Development (NIPRD), Abuja, Nigeria where a voucher specimen was deposited in the herbarium for reference.

**Chemicals and reagents**

Chemicals and reagents were purchased from Sigma Chemical Company (St. Louis, USA).

RESULTS

Table 1 shows that administration of dexamethasone induced increase serum glucose level however the hyperglycaemia was reversed by significant dose dependent of the extracts of *P. biglobosa*, this was highly significant in the groups receiving 100 mg/kg *P. biglobosa* extract and ketoconazole.

Dexamethasone induced higher increase in serum glucose level; high significant hypoglycaemia was observed in groups treated with 100 mg/kg *P. biglobosa* extract compared with the groups receiving normasaline as indicated in Table 2.

Table 3 and 4 show 4-point scale of the semi-quantitative analysis of histological section, 0 scale shows thickness of cut edges with absence of polymorphonuclear leucocytes (PMNL), fibroblasts, new vessels, and new collagen. Migration of cells <50% with mild surrounding tissues,mild subcutaneous tissues and minimal granulation tissue were described by scale 1,

Figure 1. Histological structures of healed skin wounds on day 14 of pre wounding (stained with hematoxylin and eosin X 10). A=Control (Pre-treated), B=Pre-treated (100 mg), C=Ketoconazole.

Figure 2. Histological structures of healed skin wounds on day 14 of post wounding (stained with hematoxylin and eosin X 10). A= Control, B= Post-treated (100 mg); C=Ketoconazole.

scale 2 was used to evaluate migration of cells >50% mild demarcation line or granulation tissue with mild granulation tissue. Scale 3 describes bridging of the excision, moderate tissue out of the granulation tissue and moderate granulation tissue while keratinization, marked surrounding tissue and marked granulation was evaluated by scale 4.

In the photomicrograph of pre-treated and post-treated groups, administration of 100 mg/kg of pre-treated and post treated *P. biglobosa* extract indicated increased fibroblast growth, collagen synthesis, and the healing process as illustrated in Figures 1 and 2.

**DISCUSSION**

In this study, rat was used as an experimental animal model, since rat skin represents one of the most common models used in experimental studies concerning the skin wound healing. It is a useful model because we can study...
the healing of three different tissue types (epidermis, dermis and striated muscle) and it is only epidermis that has the capability to regenerate (Vidinský et al., 2006).

In the pre-treated groups, the antihyperglycemic activity of the *P. biglobosa* extract in dexamethasone-treated animals may be due to decrease peripheral insulin resistance or by suppression of enzymes involved in hepatic gluconeogenesis as well as by stimulation of glucose uptake and use in peripheral tissues similar to study conducted by Shanmugasundaram et al. (1983) and Persaud et al. (1999). Decrease in serum glucose level may also be mediated through an increase in insulin release from pancreas according to the research carried out by Caro and Amatruda (1982).

Corticosteroid-induced diabetes mellitus mechanism involves insulin resistance, caused by the alteration in binding of insulin to its receptor (receptor defect) or by the impairment of the intracellular response to insulin (Rizza et al., 1982). Hyperglycaemia inhibits wound healing process associated with prolonged inflammatory phase (Naguib et al., 2004) defected angiogenesis (Gore et al., 2006) and diminished fibroblast proliferation (Hehenberger and Hansson, 1997).

In order to effectively manage chronic wounds, periodic assessment of the healing process is necessary (Mulkins et al., 2005). A semi-quantitative score was adopted in this study for scoring the degree of changes observed on an ordinal scale, namely, low, medium or high grade. Even though quantitative scoring system is highly specific and standardized due to difficulty to objectify the exact interval between two values, semi-quantitative scoring systems remain in wide use in the world of the biomedical research (Lemo et al., 2010).

Corticosteroid induced diabetic wound-healing indicated a reduction in the contraction of open wounds, decreased capillary volume, decreased number of olymorphismonucleocytes, increased edema, decreased number of fibroblasts, decreased neovascularization, and increased rate of infection. This reduction is related to a delay in the appearance of inflammatory cells and to a reduction in fibroplasia, a new connective tissue matrix, collagen synthesis and deposition, and wound breaking strength (Bitar, 1998).

Wound healing is composed of three stages namely inflammation, proliferation and remodeling (Whaley and Burt, 1996). The proliferative stage typically demonstrates angiogenesis, collagen deposition, granulation tissue formation, epithelialization and wound contraction. In angiogenesis, new blood vessels are formed from endothelial cells (Cotran, 1999).

Increased collagen deposition, regeneration, and well-aligned tissue observed in both pre and post-treated groups are in accordance with a study, which reported prohealing parameters (Muhammadu et al., 2016).

The influence of various factors on the wound healing was evaluated histologically on the fourteenth day similar to study conducted by Whelan et al. (2003). In the present study the most significant changes occur during the first week of wound healing, this correlates with the study conducted by Medrano et al. (2003).

Differentiation of fibroblasts into myofibroblasts was observed during the healing process. Myofibroblasts synthesize extracellular matrix components such as collagen types I and III. Indicator for the assessment of wound healing is fibroblast proliferation (Park et al., 2005). The major cell type found in the granulation of wound tissues is fibroblasts. They play important role in wound healing including secretion of a series of growth factors that facilitates angiogenesis, proliferation and matrix deposition (Mansbridge et al., 1999).

Studies conducted on the phytochemical screening of *P. biglobosa* showed the presence of phytoconstituents such as anthraquinones, tannins, flavonoids, terpenes, saponins, phenols and steroids (Builders et al., 2016); these may be attributed to the wound healing activity of *P. biglobosa*. The enhanced wound healing activity of this extract could be related to a function of either the individual or the additive effects of the phytoconstituents which is similar to research conducted by Liu et al. (2013). These bioactives have been reported to possess pharmacological properties such as antimicrobial, antioxidant, analgesic, and anti-inflammatory activities which promote the wound-healing process mainly due to wound contraction and increased rate of epithelization (Liu et al., 2013).

**Conclusion**

The wound healing activity of *P. biglobosa* extract in a simple experimental model has been established. Further studies are in progress in our laboratory to isolate and characterize the relevant bioactive components and elucidate the mechanisms of actions of these active ingredients.
