Received 20 January, 2016; Accepted 22 March, 2016

Understanding weather extremes and climate variability both in space and time based on historical surface observed climate data at watershed is very crucial as it is used as in put for applying the seasonal forecast given by National Hydrological and Meteorological Agencies, in decision making in agricultural activities, water resources projects, rainfall-runoff modeling, and for drought risk identification and assessment. This study examined the spatio-temporal variability of dry spell length in Kiremt (June to September) season and trend detection, as a means of indication for climate change, in rainfall extremes over Tekeze river basin, Ethiopia. Daily rainfall indices were used over the basin based on data available from 24 meteorological stations having variable record length spanning from 1960-2009 with available data from 1992-2009 for most of the stations. Data quality control was done for infilling missing values and main quality tests of outliers and homogeneity tests. Temporal variability was analyzed by coefficient of variability and temporal trends were analyzed using Mann-Kendall method. Spatial distribution and variability was investigated using ordinary kirging interpolation technique. The results showed that: (1) The dry spell lengths for the months of kiremt season showed high temporal variability; (2) The dry spell lengths in the months of Kiremt season were shown to be higher in north-east and north-west of the river basin than the other parts; (3) The dry spell lengths were higher in the months of June and September and changed more rapidly in the basin than dry spell lengths in July and August; and (4) A significantly increasing trend on the 95<sup>th</sup> percentile of daily rainfall was found at Gonder meteorological station and significantly decreasing trend on the 90<sup>th</sup> percentiles of daily rainfall was found at Mekelle meteorological station.

**Key words:** Dry spell lengths, extreme rainfall, climate change, spatial variability.

## INTRODUCTION

The use of implementing expensive and elaborate rainfall monitoring networks at a basin is to capture and understand the spatial and temporal variability of rainfall.

Rainfall is the most important hydrological variable and it varies considerably over space and time. This variability makes it a major source of risk for agricultural production

especially for a country like Ethiopia whose economy is dependent on rain-fed agriculture. This sector is highly sensitive to the spatial and temporal variability of rainfall and much below normal rainfall years in the country resulted in low agricultural production and as a consequence it affected millions of people in the country (Wolde-Mariam, 1984; Degefu, 1987; Hurni, 1993; Camberlin, 1997; Aredo and Seleshi, 2003). The spatial and temporal variability of water resources is also affected due to rainfall variability. Rainfall variability has greater impact on hydrology and water resources (Novotny and Stefan, 2007). The study of rainfall variability in time and space over long period of time is basic for water resources management and decision making strategies. According to Michaelides et al. (2009) understanding rainfall variability in time and space helps greatly for agricultural planning, rainfall-runoff modeling, water resources assessments and climate change and environmental impact assessments.

Even though rainfall monitoring networks are sparsely distributed at the country, many researches have been conducted to understand rainfall variability using the existing stations in the country. The previous researches on the rainfall variability have been done on different spatial and temporal scales. Examples: Osman and Sauerborn (2002) studied the rainfall variability of the central highlands of Ethiopia for the main rain season (June to September) using 11 stations of data from (1898-1997) and noted a decreasing trend of seasonal rainfall in their study. Seleshi and Zanke (2004) studied the rainfall variability of Ethiopia at seasonal and annual time scales using 11 stations with data from (1965-2002) and noted no trend of rainfall at annual and seasonal time scales for Central, Northern and Northwestern Ethiopia highlands. But with significant trend over Eastern, Southern and Southwestern Ethiopia. Cheung et al. (2008) studied the rainfall variability of 13 watersheds of the whole Ethiopia using 134 stations of data between 1960 and 2002 at annual and seasonal time scales. For Tekeze river catchment they utilized nine rainfall stations and found no trend in the rainfall time series. The above previous studies, with contradicting conclusions, did not studied the rainfall variability at daily time and spatial scales and used few number of stations compared to their area of studies.

This study examined the variability dry spell lengths and trend detection in rainfall extremes at the Tekeze river basin both in time and space. It tried to answer such questions: (i) to what extent do the dry spell lengths vary in time and space? (ii) Which part of the river basin is more affected by dry spell lengths? (iii) How do the dry spell lengths vary from location to location in the river basin? And (iv) is there any climate change indication in rainfall extremes in the basin?

### **Description of the study area**

Tekeze basin is one of the major river basins of Ethiopia.

The basin is located in the Northern western part of Ethiopia (Figure 1). The basin consists of the main catchments of Tekeze, Angerb and Goang rivers. This study focuses only on the Tekeze river basin. Tekeze river basin is located at  $11^{\circ}40'12.20''$  N to  $14^{\circ}45'42.29''$  N and  $36^{\circ}32'07.70''$  E to  $39^{\circ}46'23.89''$  E in the Northern western part of Ethiopia. The Tekeze river basin has an area of  $63,109.1 \text{ km}^2$  with its outlet located at  $14.259^{\circ}$  N and  $36.560^{\circ}$  E. The river basin has a minimum elevation of 537 m.a.s.l and a maximum elevation of 4517 m.a.s.l. The annual rainfall variability in the Tekeze basin is very high. The mean annual rainfall in the basin ranges from about 600 mm in the north east to over 1200 mm in the high lands of south west (Belete, 2007). Generally the rainfall in the basin is high affected by local factors like topography and micro-climate in the basin (Amare, 1996). The year-to-year variability of annual rainfall totals in the basin is very high showing coefficient of variability ranging from 0.2 in the high lands of the basin to 0.4 over its low land part (Belete, 2007). The mean annual temperature in the basin varies from about  $10^{\circ}\text{C}$  in the highlands of the basin to over  $26^{\circ}\text{C}$  on its lowlands.

### **METHODOLOGY**

In order to examine the spatial and temporal variability of rainfall in the Tekeze river basin, the study approach is summarized as follows and details are presented in the subsections below. A Digital Elevation Model (DEM), which is 90 m spatial resolution, of the Tekeze river basin is downloaded from the website of <http://srtm.sci.cgiar.org/SELECTION/input/Coord.asp>. And the location of each meteorological station was obtained from the website of [www.nma.org.et](http://www.nma.org.et) of the National Meteorological Agency of Ethiopia. After delineating the Tekeze river basin from the DEM and identifying the meteorological stations which could represent the basin, quality control for the daily data of each station have been done. Assessment for quality of the data of each station was done by filling missing data, testing for outliers and testing for temporal homogeneity. After checking for outlier and making adjustment and identifying only stations with homogeneous rainfall data, rainfall indices were derived and the temporal and spatial variability of the indices over the basin were done.

#### **Data collection**

In this study, daily rainfall data of the Tekeze river basin for the period from 1960-2009 with available data from 1992-2009 for most of the stations were obtained from the archives of the National Meteorological Agency (NMA) of Ethiopia. The dataset contains 24 meteorological stations. The spatial distribution of those meteorological stations is shown in Figure 2. And Table 1 illustrates a generalized geographic location, period of recorded rainfall, and percent of missing values information of each selected stations used for this study.

#### **Data quality and control**

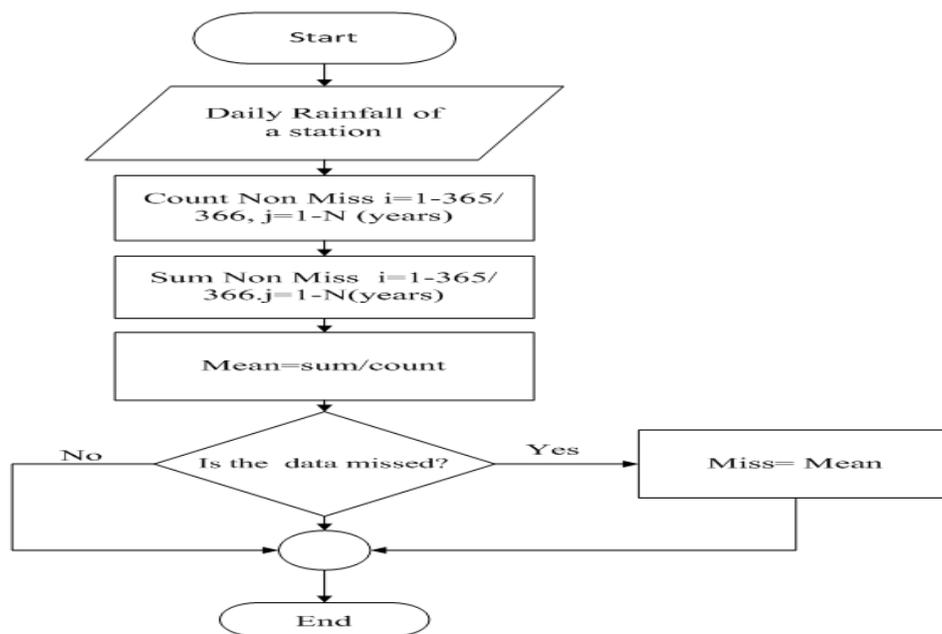

Figure 3. Flow chart showing infilling daily rainfall data by long-term mean.

of the recorded data can be done by sample mean taking in to account the correlation between the daily rainfalls is negligible

(Presti et al., 2010). Therefore, all the stations having daily missing rainfall data at most 10% are filled by mean of each day. Figure 3

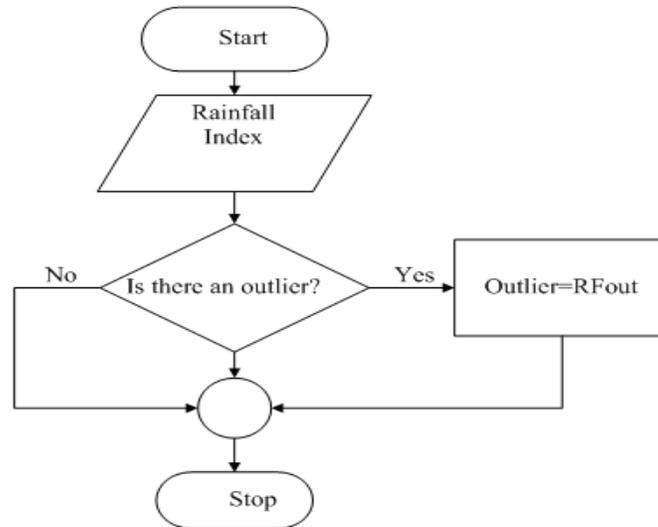

Figure 4. Flow chart showing how to adjust outliers.

shows how to fill the missing daily rainfall of each station.

#### Outlier detection and adjustment

The identification of outliers has been the primary emphasis of quality control work (Gonzalez-Rouca et al., 2001; Göktürk et al., 2008). Outliers are values greater than a threshold value specific for each time series, defined by

$$RF_{out} = RF_{0.75} + 3 * IQR$$

Where  $RF_{out}$  is a threshold value,  $RF_{0.75}$  is the third quartile and IQR is the inter quartile range and any outlier can be replaced by its threshold value as stated by Gonzalez-Rouca et al. (2001) and Göktürk et al. (2008). In order to keep the information of extreme values in the data, outliers can be replaced by the threshold value in the data. For keeping the outliers of each rainfall indices of each station, a threshold value was calculated and any outlier in each index could be replaced by the threshold value ( $RF_{out}$ ). Flow chart how to adjust outlier is shown in Figure 4.

#### Homogeneity test

A rainfall time sequence is called homogeneous when its variability is as the result of weather and climate (Conrad and Pollak, 1950). Long period recorded rainfall can be non homogeneous when affected by non-climatic factors that make them unrepresentative of the actual climatic variations occurring over the time (Peterson et al., 1998). Non homogeneity of the time sequence can be occurred due to change in location of the rainfall station, instruments, formula used to calculate the statistical parameters, observing practices and station environments (Göktürk et al., 2008). In order to be sure that daily rainfall recorded by all the stations in this study are representative in their areas of location and their variability is only due to climatic and weather process not other factors, three homogeneity test methods were used the Pettitt's test (Pettitt, 1979), the Standard Normal Homogeneity Test (SNHT) (Alexandersson, 1986), and the Buishand's test (Buishand, 1982). The homogeneity tests by the three methods were done on daily maximum rainfall (MaxRF), daily mean rainfall (MEANRF) and

annual rainfall (ANNUALRF) of each station. The explanations of the three methods of homogeneity test are shown in Figure 5.

#### Derivation of rainfall indices from daily rainfall data

Six rainfall indices describing different aspects of rainfall regime were derived from the daily rainfall in this study. The indices have been used in various parts of Africa. Many authors define a dry spell as  $n$  consecutive days without appreciable rainfall (Stern, 1980; Sivakumar, 1992; Sharma, 1996; Ceballos et al., 2004; Gong et al., 2005). In many studies, days with rainfall less than 0.1 mm per day are considered a dry spell. Mean values of each index were calculated at annual time scale and seasonal time scales (June to September). Table 2 provides the name of each index with its explanation.

#### Rainfall indices temporal variability and trend detection

The coefficient of variation (CV) is used as statistical descriptor of the rainfall indices temporal variability of the stations over Tekeze basin. The CV of a variable is the standard deviation the variable divided by its mean. High CV of a variable indicates high temporal variability of the variable. The existence of a trend of a time series of the rainfall indices can be quantified by least squares regression in stations having at least 30 year of recorded data and the trend statistical significance can be test by Mann-Kendall (MK) test which is used in this study. The rainfall indices at Gonder, Mekelle and Edagahamus meteorological stations having daily rainfall of period 1960-2008, 1960-2009 and 1973-2007 respectively were subjected to non-parametric Mann-Kendall test to detect trend as means of indication for climate change.

#### Rainfall indices spatial distribution and variability

In order to examine the spatial distribution and variability of the rainfall indices from the meteorological stations, it was necessary to estimate the point rainfall index at unrecorded locations from the values at the surrounding stations. Kirging interpolation technique was used in this paper. This method is increasingly preferred

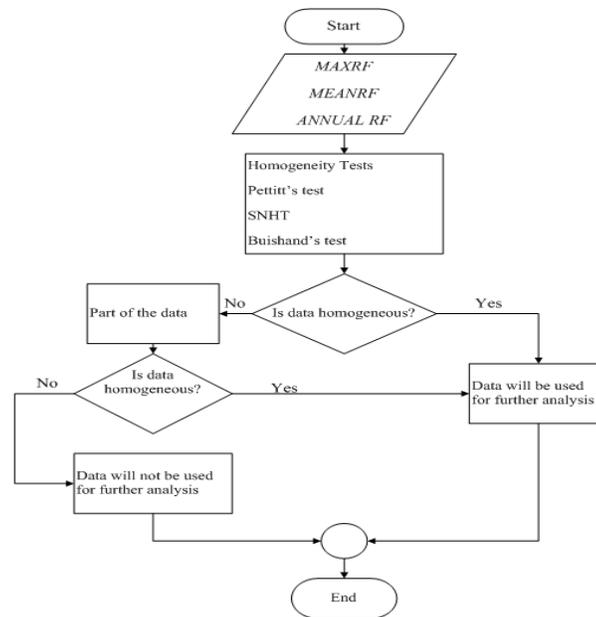

Figure 5. Flow chart of non homogeneity tests.

Table 2. Name of the six selected indices with their explanations.

S/N	Explanation	Index Name
1	Dry day	A day with rainfall of < 0.1mm in a day in a year
2	Dry spell length for June	Two or more consecutive dry spells in June
3	Dry spell length for July	Two or more consecutive dry spells in July
4	Dry spell length for August	Two or more consecutive dry spells in August
5	Dry spell length for September	Two or more consecutive dry spells in September
6	90 <sup>th</sup> percentile	The 90 <sup>th</sup> percentile of daily rainfall in a year
7	95 <sup>th</sup> percentile	The 95 <sup>th</sup> percentile of daily rainfall in a year

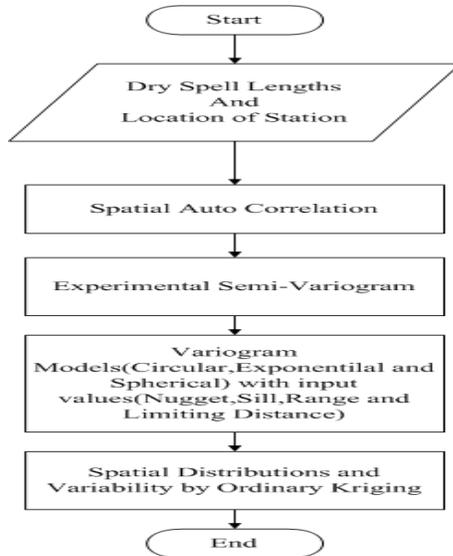

because it capitalizes on the spatial correlation between neighboring observations to predict attributed values at unsampled locations (Goovaerts, 1999). It is not simply based on an estimation of the unknown value as a function of the distance. In addition to that it implements the function of unknown spatial autocorrelation between the values of the sample points. In addition, (Tabios and Salas, 1985) have shown that geostatistical prediction techniques (kriging) provide better estimates of rainfall than conventional (Thiessen Polygon and Inverse Distance Weighted (IDW) methods. Of the types of kriging, especially ordinary kriging was used in this study by using the Integrated Land and Water Information System (ILWIS) which is an integrated Geographical Information System (GIS) and Remote Sensing software. The best fitting models (Exponential, Spherical and Circular) are identified by adjusting the nugget, range and sill parameters from the experimental semi-variogram of the chosen model by visual inspection. Model variogram is used to develop interpolated surface to predict spatial continuity in the river basin by ordinary kriging. The limiting distance that is the maximum search radius to find stations which will be taken into account during the interpolation of the indices is determined by doing pattern analysis of the stations with reference to the area of the basin. The spatial variability of all the indices can be analyzed using ordinary kriging

interpolation technique. In Ordinary Kriging the randomized spatial function is non-stationary and the mean varies over the area of interest. Ordinary Kriging amounts to re-estimating the mean at each new location. In Ordinary Kriging, you can influence the number of points that should be taken into account in the calculation of an output pixel value by specifying a limiting distance and a minimum and maximum number of points. Only the points that fall within the limiting distance to an output pixel will be used in the calculation for that output pixel value. Ordinary Kriging needs three steps Spatial Correlation, Empirical Semi-Variogram and modeling semi-variogram as shown in the flow chart Figure 6.

## RESULTS AND DISCUSSION

### Temporal variability of dry spell lengths for June, July, August and September (months of the kiremt season) over Tekeze river basin

There is very high year-to-year variability of dry spell lengths for the months of Kiremt season (June, July,

**Figure 6.** Flow chart in using ordinary Kriging and Gonder stations.

August and September) over Tekeze catchment showing coefficient of variability greater than 0.3. As shown in Table 3.

### **Temporal variability of 90<sup>th</sup> and 95<sup>th</sup> percentiles of rainfall over Tekeze river basin**

The temporal variability of the 90<sup>th</sup> and 95<sup>th</sup> percentiles of rainfall over the Tekeze river basin is high with CV from 0.2 to 0.3. Very high temporal variability of the 90<sup>th</sup> and 95<sup>th</sup> percentile of rainfall is shown in northwestern station (Humera), northern station (Abiadi), northeastern stations (Edaghamus and Wukro) and southeastern station (Adigudem) with (CV>0.3).

### **Trend detection**

The six rainfall indices at Gonder, Mekelle and Edaghamus meteorological stations having daily rainfall of period 1960-2008, 1960-2009 and 1973-2007 respectively were subjected to non-parametric Mann-Kendall test to detect trend. The time series of the indices only with significant trend are shown in Figures 7 to 8. The slope of each index was determined by fitting a liner regression line. The Mann-Kendall test result is shown in Tables 4. A negative trend on the 90<sup>th</sup> percentile of daily rainfall at 95% confidence interval was detected at Mekelle station as shown in Figure 7. A positive significant trend for 95<sup>th</sup> percentile of daily rainfall at Gonder station was detected as shown in Figure 8. No significant trends of the other indices were detected at Mekelle.

### **Dry spell length of June, July, August and September (DSLJJAS) (months of kiremt season) spatial variability over Tekeze river basin**

Circular for mean dry spell length of June and mean dry spell length of August and exponential for mean dry spell length of July and spherical for the mean dry spell length of September semi variogram models are fitted. Table 5 represents the parameters that were obtained from experimental semi variogram fitting to the mean DSLJJAS data recorded at the stations in the study area and the figures with their error figures represents the interpolated spatial continuity of the DSLJJAS distributions in the catchment. Below detail interpretation of the fitted models, parameters of the models and figures with their error figures is given for their spatial variability of the DSLJJAS in the Tekeze river basin.

### **Interpretation of variogram models for mean DSLJJAS**

The four variogram models of DSLJJAS (show a progressive decrease of spatial autocorrelation (equivalently an increase of semi-variance) until some distance (range values) in DSLJJAS in the stations in the river basin as shown in Figures 9 to 12. The dry spell length for June and August decrease their spatial dependence in circular manner in the basin but the dry spell length for July and September decrease their spatial dependence exponentially and spherically in the basin respectively. Even though the variogram models fitted to the variogram models show a common characteristics of decreasing spatial dependence with distance in the DSLJJAS in the catchment, the way they lose their spatial dependence with distance in the catchment of the four variables is different because of fitted to different variogram models with different model parameters (nugget, sill and range).

### **Interpretation of the nugget, sill and range values of the models of DSLJJAS**

The DSLJJAS show a nugget effect in their variogram models. These nugget values of the models show two important things in the basin. The sampling interval or the lag space between the stations in the study area was taken to be 60 km because of sparse rainfall station distributions in the basin. But the nugget values in the DSLJJAS variogram models indicates the availability of few stations in the catchment basin with distance between them less than the sampling interval (60 km) and a sources of spatial variability of the variables in distance less than the sampling interval. Higher nugget value means high spatial variability of the variable less than the sampling interval. Due to this the dry spell lengths for June and September have high spatial

**Table 3.** Mean and CV of 90<sup>th</sup> and 95<sup>th</sup> percentiles and dry spell lengths for each months.

variability in distance less than the sampling interval in the basin than the dry spell lengths in July and August. The different range values of the models in DSLJJAS show existence of spatial variability until its value in the river basin and

beyond it no existence of spatial dependence of the variables in the basin. Higher range value of a variable indicates the existence of the spatial dependence of the variable of the stations separated by higher distance. Due to this all the DSLJJAS

have approximately the same spatial dependence in high separated stations in the basin. The sill is the value of the variogram model attains at range. The higher the sill value of a variable, the steep becomes the model and the more rapidly changes

the variable in space. Because of this the dry spell lengths in June and September change more rapidly in the basin than the dry spell lengths in July and August do.

**Spatial distribution estimates of DSLJJAS estimates over the river basin**

The DSLJJAS figures with their error figures of the

Tekeze river basin are obtained by interpolation using their fitted models by ordinary kriging. The figures of DSLJJAS indicate the spatial distribution estimates over the entire basin using the 24 stations as shown in Figure 13. The error Figure 14 of the DSLJJAS indicates the standard error of estimation of the DSLJJAS by the ordinary kriging. As indicated on the figures of DSLJJAS, the dry spell length for June varies from about 5 days in the west part of the basin to about 17 days in the east

**Figure 14.** Standard error of spatial distribution of dry spell lengths for June, July, August and September over Tekeze river basin.

part of the basin. The dry spell length for June increases progressively from west to east part of the basin. The dry spell for July varies from about 2 days in the southwest part of the basin to about 5 days in the northwest and northeast part of the basin. South, southwest and central parts of the basin have lower dry spell length in July than other parts. The dry spell length for August varies from about 2 days in the southwest and central to about 6 days in the far northwest and far northeast parts of the basin. Dry spell length for September varies from about 7 days in the south and west part of the basin to about 20 days in the northeast part. Higher standard error values in the error figure of the DSLJJAS indicate sources of spare stations in the area than the other areas. These standard errors of estimations help for decision making in the areas when the Figure 13 of DSLJJAS is used.

## CONCLUSIONS AND RECOMMENDATION

The main findings of the study are summarized below. The dry spell length for the months of kiremt (June to September) season is highest in the months of June and September than the months of July and August in the Tekeze river basin. In general, the dry spell length distribution for the months of Kiremt season increases from west to east part of the river basin. There is very high year-to-year variability of dry spell length for the months of kiremt season over the basin. The dry spell lengths in June and September change more rapidly in the river basin than the dry spell lengths in July and August. A significantly decreasing trend on the 90<sup>th</sup> percentiles of daily rainfall is found at Mekelle meteorological station and a significantly increasing trend

on the 95<sup>th</sup> percentiles of daily rainfall is found at Gonder meteorological station.

The results, figures developed here can be very useful for meteorological, hydrological and agricultural management activities at the Tekeze river basin. Especially the information on temporal and spatial variability of dry spell lengths, are needed by the farmers on the river basin for deciding on crop types, varieties and dates for land preparations, planting and harvesting and for planning of civil and water resources projects. As in this study only 24 meteorological stations having different time periods were used, it also very important to consider world meteorological standard distributions of the stations in the basin with the same time period of data so that the result can be improved. Again the interpolation technique used in the study of the spatial variability was ordinary kriging but it is very important to do evaluation of interpolation techniques like simple kriging, co-kriging and others with ordinary kriging and choosing the best interpolation technique in the basin can improve the results.

### Conflict of Interests

The authors have not declared any conflict of interests.
